FIELDING, WILLIAM STEVENS (1848-1929), Canadian journalist and statesman, was born in Halifax, Nova Scotia, on Nov. 24, 1848. From 1864 to 1884 he was one of the staff of the *Morning Chronicle*, the chief Liberal paper of the province, and worked at all departments of newspaper life. In 1882 he entered the local legislature as Liberal member for Halifax, and from 1884 to 1896 was premier and provincial secretary of the province, but in the latter year became finance minister in the Dominion administration of Sir Wilfrid Laurier and was elected to the House of Commons for Shelburne and Queen's county. He opposed Confederation in 1864-67, and as late as 1886 won a provincial election on the promise to advocate the repeal of the British North America Act. His administration as finance minister of Canada was important, since in 1897 he introduced a new tariff, granting to the manufactures of Great Britain a preference, subsequently increased; and later he imposed a special surtax on German imports owing to unfriendly tariff legislation by that country. In 1902 he represented Canada at the Colonial Conference in London. He was a plenipotentiary for the negotiations of the Franco-Canada Commercial treaties in Paris (1907, 1909 and 1922); served on several Royal commissions, and negotiated various other commercial agreements. He was one of the Canadian delegates to the Assembly of the League of Nations in 1922. From 1917-25 he was M.P. for Shelburne and Queen's county, and from 1921-25 held office as minister of finance. In 1923 he was made privy councillor. He died at Ottawa on June 23, 1929.

FIELD-MOUSE (*apodemus*), the designation of such mouse-like British rodents as are not true or "house" mice. (See *Mouse* and *Vole*.)

FIELD OF THE CLOTH OF GOLD, the name given to the place between Guînes and Ardres where Henry VIII, of England met Francis I. of France in June 1520. Before the castle of Guînes a temporary palace, covering an area of nearly 12,000 sq. yd., had been erected for Henry. It was decorated sumptuously, and like the chapel, furnished with a profusion of golden ornaments. The size of Henry's following may be gathered from the fact that in one month 2,200 sheep and other viands in a similar proportion were consumed. In the fields beyond the castle, 2,800 tents were erected for less distinguished visitors. After Cardinal Wolsey had visited the French king at Ardres, the two monarchs met at the Val Doré, a spot midway between the two camps, on June 7. The subsequent tournaments, banquets and entertainments lasted until the 24th. The meeting made a great impression on contemporaries, but its political results were very small. Henry shortly after enjoyed an equally friendly meeting with Francis' rival, the Emperor Charles V.

The *Ordonnance* for the *Field* is printed by J. S. Brewer in the *Calendar of State Papers, Henry VIII.* Vol. iii. (1867). See also J. S. Brewer *Reign of Henry VIII.* (1884).

FIELDS, JAMES THOMAS (1817-1881). American publisher and author, was born in Portsmouth (N.H.), Dec. 31, 1817. At the age of 17 he went to Boston as clerk in a bookseller's shop, where he began to write for the newspapers. In 1839 he became junior partner in the publishing and bookselling firm known after 1846 as Ticknor & Fields, and after 1868 as Fields, Osgood & Company. He was the publisher of the foremost contemporary American writers, with whom he was on terms of close personal friendship, Whittier, for instance, depicting him in *The Tent on the Beach*, and he was the American publisher of some of the best-known British writers of his time, some of whom, also, he knew intimately. The first collected edition of De Quincey's works (20 vol., 1850-55) was published by his firm. As a publisher he was characterized by a somewhat rare combination of business acumen and discriminating literary taste, and as a man he was known for his geniality and charm of manner. In 1862-70, as the successor of James Russell Lowell, he edited the *Atlantic Monthly*. After his retirement Fields devoted himself to lecturing and to writing. Apart from his poems, his chief books were the collection of sketches and essays entitled *Underbrush* (1877, enlarged ed. 1881) and the chapters of reminiscence composing *Yesterdays with Authors* (1872). He died in Boston April 24, 1881.

His second wife, ANNIE ADAMS FIELDS, whom he married in 1854, was a prominent literary figure. She was the author, among other works, of *Under the Olive* (1880), a book of verses; *James T. Fields: Biographical Notes and Personal Sketches* (1881); *Authors and Friends* (1896); and *Orpheus, a Masque* (1900). See "Mr. and Mrs. James T. Fields" by Henry James in the *Atlantic Monthly* (July, 1915), and *Memories of a Hostess*, drawn chiefly from the diaries of Mrs. James T. Fields by M. A. De Wolfe Howe (1922).

FIELDS, LEWIS: see WEBER AND FIELDS.

FIELD SYSTEM: see OPEN FIELD SYSTEM.

FIENNES, NATHANIEL (c. 1608-1669), English politician, second son of William, first Viscount Saye and Sele, was educated at Winchester and at New College, Oxford, where as founder's kin he was admitted a perpetual fellow in 1624. After some time spent on the continent, where he came into touch with Calvinist leaders he returned to Scotland in 1639, and established communications with the Covenanters and the Opposition in England, and as member for Banbury in both the Short and Long Parliaments he took a leading part in the attacks upon the Church of England. He was one of the commissioners appointed to attend the king to Scotland in Aug. 1641; and was nominated one of the committee of safety in July 1642. In the Civil War he commanded a troop of horse in Essex's army, was present at the relief of Coventry in August, at Worcester and at Edgehill. In Feb. 1643 Fiennes was sent down to Bristol, arrested Colonel Essex the governor, executed the two leaders of a plot to deliver up the city, and received a commission himself as governor on May 1, 1643. On the arrival of Prince Rupert (July 22) Fiennes capitulated. He was tried at St. Albans by the council of war in December, was pronounced guilty of having surrendered the place improperly, and sentenced to death. He was, however, pardoned, and subsequently exonerated. He held various appointments under the Commonwealth. He took no part in the Restoration, and died at Newton Tony in Wiltshire on Dec. 16, 1669. Fiennes married (1), Elizabeth, daughter of Sir John Eliot, by whom he had one son, afterwards 3rd Viscount Saye and Sele; and (2), Frances, daughter of Richard Whitehead of Tuderley, Hants, by whom he had three daughters. Fiennes was the author of a large number of pamphlets, some of which have been reprinted in the series of *Thomson and Somers tracts*.

FIERI FACIAS: see EXECUTION.

FIESCHI, GIUSEPPE MARCO (1790-1836), Corsican adventurer, was born at Murato, Corsica on Dec. 13, 1790. He served under Murat, then returned to Corsica, where he was condemned to ten years' imprisonment and perpetual surveillance by the police for theft and forgery. He eluded the police, obtained a small post in Paris, and took lodgings on the boulevard du Temple. There, with two members of the Société des Droits de

l'Homme, Morey and Pépin by name, contrived an "infernal machine." On July 28, 1835, as Louis Philippe was passing along the boulevard to the Bastille, accompanied by his three sons and a numerous staff, the machine was exploded. Marshal Mortier was killed, with 17 other persons, and many were wounded; but the king and the princes escaped. Fieschi himself was severely wounded. He was condemned to death, and was guillotined on Feb. 19, 1836. Morey and Pépin were also executed, another accomplice was sentenced to 20 years' imprisonment and one was acquitted.

See *Procès de Fieschi* (2 vols., 1836); also P. Thureau-Dangin, *Hist. de la monarchie de Juillet* (vol. iv. ch. xii., 1884).

FIESCO (DE' FIESCHI), GIOVANNI LUIGI (c. 1523-1547), count of Lavagna, was descended from one of the greatest families of Liguria, first mentioned in the 10th century. He married Eleonora Cibò, marchioness of Massa, in 1540, a woman of great beauty and family influence. The Fiesco belonged to the French or popular party, while the Doria were aristocrats and Imperialists. When Fiesco determined to conspire against Doria he found friends in many quarters. Pope Paul III. was the first to encourage him, while both Pierluigi Farnese, duke of Parma, and Francis I. of France encouraged him. Among his associates in Genoa were his brothers Girolamo and Ottobuono, Verrina and R. Sacco. A number of armed men from the Fiesco fiefs were secretly brought to Genoa, and it was agreed that on Jan. 2, 1547, during the interregnum before the election of the new doge, the galleys in the port should be seized and the city gates held. The first part of the programme was easily carried out, and Giannettino Doria, aroused by the tumult, rushed down to the port and was killed, but Andrea escaped from the city in time. Giovanni Luigi, while crossing a plank from the quay to one of the galleys, fell into the water and was drowned. The news spread consternation among the Fiesco faction, and Girolamo Fiesco found few adherents. They came to terms with the senate and were granted a general amnesty. Doria returned to Genoa on the 4th thirsting for revenge, and in spite of the amnesty he confiscated the Fiesco estates. Girolamo Fiesco and Verrina were captured, tried, tortured and executed. Ottobuono Fiesco, who had escaped, was captured eight years afterwards and put to death by Doria's orders.

There are many accounts of the conspiracy, of which perhaps the best is contained in E. Petit's *André Doria* (1887), chs. xi. and xii., where all the chief authorities are quoted; see also E. Callegari, *La Congiura del Fiesco* (Venice, 1892) and A. Gavazzo, *Nuovi documenti sulla congiura del conte Fiesco* (Genoa, 1886); E. Bernabò-Brea, in his *Sulla congiura di Giovanni Luigi Fieschi* (1865) publishes many important documents, while L. Capelloni's *Congiura del Fiesco*, edited by A. Olivieri (1858) and A. Mascardi's *Congiura del conte Giovanni Luigi de' Fieschi* (Antwerp, 1629) may be commended among the earlier works. The Fiesco conspiracy has been the subject of many poems and dramas, of which the most famous is that by Schiller. See also under DORIA, ANDREA; FARNESE.

FIESOLE (anc. *Faesulae*, *q.v.*), a town and Episcopal see of Tuscany, Italy, province of Florence; it is 3 m. N.E. of the town of that name by electric tramway. Pop. (1921) town, 2,786, commune 10,059. It is on a hill with two summits 970 ft. above sea-level, and commands a fine view. The cathedral of S. Romolo is an early and simple Tuscan Romanesque basilica, begun 1028 and restored 1256. The picturesque battlemented campanile belongs to 1213. The 13th-century Palazzo Pretorio contains a small museum of antiquities. The inhabitants of Fiesole are largely engaged in straw-plaiting.

Below Fiesole, between it and Florence, lies San Domenico di Fiesole (485 ft.). In the Dominican monastery the painter, Fra Giovanni Angelico da Fiesole (1387-1455), lived until he went to S. Marco at Florence. Here, too, is the Badia di Fiesole, re-erected about 1456-1466 by a follower of Brunelleschi. It is an irregular pile of buildings, in fine and simple early Renaissance style; a small part of the original façade of 1028 in black and white marble is preserved. The slopes of Fiesole are covered with beautiful villas, the Villa Medici and the Villa Palmieri are among the finest. To the south-east lies Monte Ceceri (1,453 ft.), with quarries of grey *pietra serena*, largely used in Florence for building. To the east of this lies the 14th-century castle of Vin-

cigliata restored and fitted up in the mediaeval style.

FIFE, eastern county, Scotland, bounded north by the Firth of Tay, east by the North sea, south by the Firth of Forth, and west by the shires of Perth, Kinross and Clackmannan. The Isle of May, Inchkeith, Inchcolm, Inchgarvie and the islet of Oxcar belong to the shire. It has an area (excluding water) of 323,012 acres. Its coast-line measures 108 miles. The Lomond hills to the south and south-west of Falkland reach, in West Lomond, a height of 1,713 ft.; their summits show intrusive sheets of dolerite and basalt penetrating the lower Carboniferous rocks, as does that of Benarty, on the confines of Kinross. Volcanic structures of various ages occur widely: in the north they are of Old Red Sandstone age and form the higher ground bordering the Firth of Tay, The Howe (or Hollow) of Fife; south of this tract, and watered in part by the river Eden, is a lowland underlain by soft Upper Old Red Sandstones: the quarries in these rocks in Dura Den are famous for their fossil fishes. The Carboniferous formations occupy the rest of the county southward. Many necks of volcanoes of the Permian period are traced in east Fife, as at Largo Law and in the example of columnar basalt at Kincaig Point on the coast. Of the rivers the Eden is the longest; formed on the borders of Kinross-shire by the confluence of Beattie burn and Carmore burn, it pursues a wandering course for 25 m. N.E., partly through the Howe of Fife, to the North sea. There is good trout fishing in its upper waters, but weirs prevent salmon from ascending it. The Leven and its tributary, the Ore, with the old and reclaimed loch Ore, and Motray water, are the other streams. The only large valley is the fertile Stratheden.

History.—The term Fife was once applied to the peninsula lying between the estuaries of the Tay and Forth and separated from the rest of the mainland by the Ochil hills. Its inhabitants were Picts of the northern branch, and their country was long known as Pictavia. Doubtless it was owing to the long continuance of an independent king that Fife itself came to be called distinctively The Kingdom. The Romans, probably only temporarily, occupied a few points, and left no impression on the civilization of the natives. Christian missionaries—especially St. Serf, St. Kenneth, St. Rule, St. Adrian, St. Moran and St. Fillan—have left memorials in the numerous coast caves between Dysart and St. Andrews, and in crosses and sculptured stones, some doubtless of pre-Christian origin, at various places. The word Fife, according to Skene, seems to be identical with the Jutland *Fibh* (pronounced *Fife*) meaning "forest," and was probably first used by the Frisians to describe the country behind the coasts of the Forth and Tay, where Frisian tribes are supposed to have settled at the close of the 4th century. The next immigration was Danish, which left lasting traces in many place-names (such as the frequent use of *law* for hill). In 1426 the first shire of Kinross was formed, consisting of Kinross and Orwell, and was enlarged to its present dimensions by the transference from Fife of the parishes of Portmook, Cleish and Tulliebole. Although the county has lain outside of the main stream of Scottish history, Dunfermline, Falkland and St. Andrews were often the scene of pageantry and romantic episodes during the reigns of the earlier Stuarts. Seventeen out of the 70 royal burghs in Scotland are in the shire. Notwithstanding the marked preference of the Stuarts, the Kingdom played the leading part in the dramas of the Reformation and the Covenant, and by the 18th century the people had ceased to regard the old royal line with any but sentimental interest, and the Jacobite risings of 1715 and 1745 evoked only lukewarm support.

Agriculture and Industries.—Only about $\frac{1}{4}$ of the total area is mountain and heath land, and the yield of wheat and barley is high. Of the green crops most attention is given to turnips. Potatoes also do well. Cattle are mainly kept for feeding purposes, and dairy farming supplies only local markets. Sheep-farming, however, and the raising of horses, especially farm horses, are important. The horses are strong, active and hardy, with a large admixture, or purely, of Clydesdale blood. North of the Eden the soil, though generally thin, is fertile, and the sandy coastal waste of Tents moor is now planted with trees. From St. Andrews southwards all the coast land is very productive. That adjacent to the East Neuk is chiefly clay and rich loam. From

Leven to Inverkeithing it varies from light sand to rich clayey loam. Excepting Stratheden and Strathleven, which are mostly rich, fertile loam, the interior is principally cold and stiff clay or thin loam with strong clayey subsoil. Part of the Howe of Fife is light and shingly and covered with heather. Some small peat mosses still exist, and near Lochgelly there is a tract of waste, partly moss and partly heath.

Fife is a great coal-producing county. The coal-field may roughly be divided into the Dunfermline basin (including Beath, Halbeath, Lochgelly and Kelty), where the principal house coals are found, and the Wemyss or Dysart basin (including Buckhaven and the hinterland), where gas-coal of the best quality is obtained. Beds of ironstone, limestone, sandstone and shale lie in many places contiguous to the coal. Iron is smelted at Kirkcaldy. Limestone, sandstone and freestone are extensively quarried in the south, and whinstone of unusual hardness and durability is obtained in several places. Pyropes, a variety of dark red garnet, sold under the name of Elie rubies, are found in the trap ufa at Elie.

The staple manufacture is linen, ranging from damasks to ducks and sackings. Its chief seats are at Kirkcaldy and Dunfermline, but it is carried on at many towns and villages, especially those situated near the Eden and Leven, on the banks of which rivers, as well as at Kirkcaldy and Dunfermline, are found the bleaching greens. Flax is spun at Dysart, and Newburgh and Kirkcaldy are famous for oil-cloth and linoleum. Most of the leading towns possess breweries and tanneries, and there are distilleries at Cameron Bridge, Kirkcaldy and Auchtermuchty. Woollen cloth is made to a small extent in several towns, and fishing-net at Kirkcaldy and Buckhaven. Paper is manufactured at Guardbridge, Markinch and Leslie, and earthenware at Kirkcaldy; there are engineering works and iron foundries at Kirkcaldy, Dunfermline and Tayport; and shipbuilding is carried on at Anstruther and Burntisland. From Inverkeithing all the way round the coast to Newburgh there are harbours, mostly of moderate dimensions, the principal port being Kirkcaldy. Salmon fishing is carried on at Newburgh and the chief seat of the herring fishery is Anstruther, but most of the coast towns take some part in the fishing.

Communications, Population and Government.—The L.N.E.R. has a monopoly in the shire. From the Forth bridge the main line follows the coast as far as Dysart, and then turns northwards to Ladybank, where it diverges to the north-east for Cupar and the Tay bridge. From Thornton Junction a branch runs to Dunfermline and another to Methil, and here begins also the coast line for Leven, Crail and St. Andrews which touches the main line again at Leuchars Junction; at Markinch a branch runs to Leslie; at Ladybank there are branches to Mawcarse Junction, and to Newburgh and Perth; and at Leuchars Junction a loop line runs to Tayport and Newport, joining the main at Wormit. From the Forth bridge the system also connects, via Dunfermline, with Alloa and Stirling in the west and with Kinross and Perth in the north. From Dunfermline there is a branch to Charlestown, which on that account is sometimes called the port of Dunfermline.

The population was 276,261 in 1931, when 810 persons spoke Gaelic and English. The chief towns are Buckhaven (17,643 with Methil), Burntisland (5,389), Cowdenbeath (12,731), Cupar (4,596), Dunfermline (34,954), Inverkeithing (3,185), Kilrenny (3,325, with Anstruther-Easter and Anstruther-Wester), Kirkcaldy (43,874 with Dysart), Leven (7,411), Lochgelly (9,297), Newport (3,275), St. Andrews (8,269), Tayport (3,164). For parliamentary purposes Fife is divided into an eastern and a western division each returning one member. It also includes the Kirkcaldy district of parliamentary burghs (comprising Buckhaven, Methil and Innerleven, Burntisland, Dysart, Kinghorn and Kirkcaldy), and the Dunfermline district (Dunfermline, Cowdenbeath, Inverkeithing and Lochgelly).

FIFE, originally the small primitive cylindrical transverse flute, now the small Bb military flute, usually conoidal in bore, used in a drum and fife band. The pitch of the fife lies between that of the concert flute and piccolo. The words *fife* and the Fr. *fifre*

were undoubtedly derived from the Ger. *Pfeiff*. The O.E. spelling was *phife*, *phiphe*, or *ffyfe*. The fife was in use in England in the middle of the 16th century. At the battle of St. Quentin (1557) the list of the English army employed states that one trumpet was allowed to each cavalry troop of 100 men, and a drum and fife to each 100 of foot. A *drumme* and *phife* were also employed at one shilling per diem for the "Trayne of Artillery." This was the nucleus of the modern military band.

FIFTH MONARCHY MEN, the name of a Puritan sect in England which for a time supported the government of Oliver Cromwell in the belief that it was a preparation for the "fifth monarchy," that is for the monarchy which should succeed the Assyrian, the Persian, the Greek and the Roman, and during which Christ should reign on earth with His saints for a thousand years. Disappointed in their hopes they agitated against the government and Cromwell; but the arrest of their leaders and preachers, Christopher Feake, John Rogers and others, cooled their ardour. After the Restoration, on Jan. 6, 1661, a band of Fifth Monarchy men, headed by a cooper named Thomas Venner, who was one of their preachers, made an attempt to obtain possession of London. Venner and ten others were executed and from that time the special doctrines of the sect died out.

For an account of the rising of 1661 see Sir John Reresby, *Memoirs, 1634-1689*, edited by J. J. Cartwright (1875); and for the proceedings of the sect see S. R. Gardiner, *History of the Commonwealth and Protectorate*, passim (1894-1901).

FIG, the popular name given to various plants of the genus *Ficus*, of the mulberry family (Moraceae), comprising about 800 species which are characterized by a remarkable development of the pear-shaped fruiting receptacle, the edge of which curves inwards, so as to form a nearly closed cavity, bearing the numerous fertile and sterile flowers mingled on its surface. The species vary

BY COURTESY OF THE COUNCIL OF THE ROYAL HORTICULTURAL SOCIETY

BRANCH OF THE COMMON FIG TREE (*FICUS CARICA*) BEARING RIPE FIGS

A. Longitudinal section through ripe fig showing seeds

B. Longitudinal section through unripe fig containing only scale leaves and long-styled female flowers

greatly in habit,—some being low trailing shrubs, others gigantic trees, among the most striking forms of the tropical forests to which they are chiefly indigenous. They have alternate leaves, and abound in a milky juice, usually acrid, though in a few instances sufficiently mild to be used for allaying thirst. This juice contains caoutchouc in large quantity.

Ficus Carica (see fig.), which yields the well-known figs of commerce, is a bush or small tree—rarely more than 18 or 20 ft. high—with broad, rough, deciduous leaves, deeply lobed in the cultivated varieties, but in the wild plant sometimes nearly entire.

The green, rough branches bear the solitary, nearly sessile receptacles in the axils of the leaves. The male flowers are chiefly in the upper part of the cavity, and in most varieties are few in number. As it ripens, the receptacle enlarges greatly, and the numerous single-seeded pericarps or true fruits become imbedded in it. The fruit of the wild fig never acquires the succulence of the cultivated

FROM ENGLER AND PRANTL, "NATÜRLICHE PFLANZENFAMILIEN" (ENGELMANN)

THE BANYAN (*FICUS INDICA*), A TREE OF THE *FICUS* GENUS, SACRED IN INDIA. AERIAL ROOTS FORM SUPPORTING PILLARS, AND BY THEIR MEANS THE TREE REACHES ENORMOUS SIZE

kinds. The fig seems to be indigenous to Asia Minor and Syria, but now occurs wild in most of the Mediterranean countries.

From the ease with which the nutritious fruit can be preserved, it was probably one of the earliest objects of cultivation, as may be inferred from the frequent allusions to it in the Hebrew Scriptures. From a passage in Herodotus the fig would seem to have been unknown to the Persians in the days of the first Cyrus; but it must have spread in remote ages over all the districts around the Aegean and Levant. The Greeks are said to have received it from Caria (hence the specific name); but the fruit so improved under Hellenic culture that Attic figs became celebrated throughout the East, and special laws were made to regulate their exportation. The fig was one of the principal articles of sustenance among the Greeks; the Spartans especially used it largely at their public tables. Pliny enumerates many varieties, and alludes to those from Ebusus (the modern Iviza) as most esteemed by Roman epicures; while he describes those of home growth as furnishing a large portion of the food of the slaves, particularly those employed in agriculture, by whom great quantities were eaten in the fresh state at the periods of fig-harvest. In Latin myths the plant plays an important part. Held sacred to Bacchus, it was employed in religious ceremonies; and the fig-tree that overshadowed the twin founders of Rome in the wolf's cave, as an emblem of the future prosperity of the race, testified to the high value set upon the fruit by the nations of antiquity.

The tree is now cultivated in all the Mediterranean countries,

but the larger portion of the market supply of figs comes from Asia Minor, the Spanish Peninsula and the south of France. Those of Asiatic Turkey are considered the best. In the United States, with protection in winter, it succeeds as far north as Pennsylvania, and is grown commercially in several Southern and South-western States, but chiefly in California, Texas and Louisiana. Since about 1900 figs of Smyrna quality have been grown in California, whose total production of all dried figs in 1927 was about 24,000,000 pounds. In Texas in the same year about 10,000,000 lb. of fresh figs were utilized in the commercial manufacture of preserves. The varieties are extremely numerous, and the fruit is of various colours, from deep purple to yellow, or nearly white. Many of the immature receptacles drop off owing to imperfect fertilization, which circumstance has led, from very ancient times, to the practice of *caprification*. Branches of the wild fig in flower are placed on the cultivated trees. Certain hymenopterous insects, of the genera *Blastophaga* and *Sycophaga*, which frequent the wild fig, enter the minute orifice of the receptacle, apparently to deposit their eggs; conveying thus the pollen more completely to the stigmas, they ensure the fertilization and consequent ripening of the fruit. When ripe the figs are picked, and spread out to dry in the sun,—those of better quality being much pulled and extended by hand during the process. Thus prepared, the fruit is packed closely in barrels, rush baskets or wooden boxes, for commerce. The best kind, known as *elemi*, are shipped at Smyrna, where the pulling and packing of figs form one of the most important industries of the people.

This fruit still constitutes a large part of the food of the natives of western Asia and southern Europe, both in the fresh and dried state. Alcohol is obtained from fermented figs in some southern countries; and a kind of wine, still made from the ripe fruit, was known to the ancients. Medicinally the fig is employed as a gentle laxative, when eaten abundantly often proving useful in chronic constipation. The wood is porous and of little value. The fig is grown for its fresh fruit (eaten as an article of dessert) in the milder parts of Europe; and in the southern and south-western United States. The tree lives to a great age, and along the southern coasts of England bears fruit abundantly as a standard; but in Scotland and in many parts of England a south wall is indispensable for its successful cultivation out of doors.

Fig trees are propagated by cuttings, which should be put into pots, and placed in a gentle hot-bed. They may be obtained more speedily from layers, which should consist of two or three year old shoots, and these, when rooted, will form plants ready to bear fruit the first or second year after planting. The best soil for a fig border is a friable loam, not too rich, but well drained; to correct the tendency to over-luxuriance of growth, the roots should be confined within spaces surrounded by a wall enclosing an area of about a square yard. The fig tree naturally produces two sets of shoots and two crops of fruit in the season. The first shoots generally show young figs in July and August, but those in the climate of England seldom ripen, and should therefore be rubbed off. The late or midsummer shoots likewise put forth fruit-buds, which, however, do not develop fully till the following spring; and these form the only crop of figs on which the British gardener can depend.

The sycamore fig, *F. Sycomorus*, is a tree of large size, with heart-shaped leaves. From the deep shade cast by its spreading branches, it is a favourite tree in Egypt and Syria, being often planted along roads and near houses. It bears a sweet edible fruit, somewhat like that of the common fig, but produced in racemes on the older boughs. The apex of the fruit is sometimes removed, or an incision made in it, to induce earlier ripening.

The sacred fig, peepul or bo (*F. religiosa*), a large tree with heart-shaped, long-pointed leaves on slender footstalks, is much grown in southern Asia. The leaves are used for tanning, and afford lac, and a gum resembling caoutchouc is obtained from the juice; but in India it is chiefly planted with a religious object, being regarded as sacred by both Brahmans and Buddhists. A gigantic bo, growing near Anarajapoor, in Ceylon, is, if tradition may be trusted, one of the oldest trees in the world. It is said to have been a branch of the tree under which Gautama Buddha became endued with his divine powers, and has always been held in the greatest veneration.

Ficus elastica, the india-rubber tree, the large, oblong-shaped, glossy leaves, and pink buds of which are so familiar in our greenhouses, furnished previous to the cultivation of South American rubber trees in the Orient, most of the caoutchouc obtained from the East Indies. It grows to a large size, and is remarkable for the snake-like roots that extend in contorted masses around the base of the trunk. The small fruit is unfit for food.

Ficus benghalensis, the banyan, wild in parts of northern India, but generally planted throughout the country, has a woody stem, branching to a height of 70 to 100 ft. and of vast extent with heart-shaped entire leaves terminating in acute points. Every branch from the main body throws out its own roots, at first in small tender fibres, several yards from the ground; but these continually grow thicker until they reach the surface, when they strike in, increase to large trunks, and become parent trees, shooting out new branches from the top, which again in time suspend their roots, and these, swelling into trunks, produce other branches, the growth continuing as long as the earth contributes her sustenance. The tree usually grows from seeds dropped by birds on other trees. The leaf-axil of a palm forms a frequent receptacle for their growth, the palm becoming ultimately strangled by the growth of the fig, which by this time has developed numerous daughter stems which continue to expand and cover ultimately a large area. The famous tree in the Royal Botanic Gardens, Calcutta, began its growth at the end of the 18th century on a sacred date-palm. In 1907 it had nearly 250 aerial roots, the parent trunk was 42 ft. in girth, and its leafy crown had a circumference of 857 ft.; and it was still growing vigorously. Both this tree and *F. religiosa* cause destruction to buildings, especially in Bengal, from seeds dropped by birds germinating on the walls. The tree yields an inferior rubber, and a coarse rope is prepared from the bark and from the aerial roots.

In North America two native species occur, the golden fig (*F. aurea*) and the short-leaved fig (*F. brevifolia*), both found in southern Florida, while the common fig (*F. Carica*) is sparingly naturalized in old fields and along roadsides from Virginia to Florida, Tennessee and Texas. Numerous species are grown as greenhouse ornamentals.

FIGARO, a famous dramatic character first introduced on the stage by Beaumarchais in the *Barbier de Séville*, the *Mariage de Figaro* and the *Folle Journée*. Figaro soon seized the popular imagination and became the recognized representative of daring, clever and nonchalant roguery and intrigue. Mozart chose the *Marriage of Figaro* as the subject of an opera, and the *Barber of Seville* was treated first by Paisiello and afterwards in 1816 by Rossini. In 1826 the name of the witty rogue was taken by a journal which continued till 1833 to be one of the principal Parisian periodicals. Various attempts were made to restore the *Figaro* during the next 20 years; and in 1854 the efforts of M. de Villemessant were crowned with success. (See NEWSPAPERS.)

See H. de Villemessant, *Mémoires d'un journaliste* (1867); Marc Monnier, *Les Aïeux de Figaro* (1868).

FIGEAC, a town of south-western France, capital of an arrondissement in the department of Lot, 47 m. E.N.E. of Cahors on the Orléans railway. Pop. (1926) 4,333. It stands on the right bank of the Célé, here crossed by an old bridge. Figeac grew up round an abbey founded by Pippin the Short in the 8th century, and throughout the middle ages it belonged to the monks. At the end of the 16th century the lordship was acquired by the duke of Sully, who sold it to Louis XIII. in 1622. The town is very rich in mediæval houses, notably the Hôtel de Balène, of the 14th

THE BANYAN, SHOWING HUGE SIZE OF AERIAL ROOTS, WHICH GROW DOWNWARD TILL THEY REACH THE SOIL, WHICH IS SPECIALLY PREPARED TO RECEIVE THEM

century. Another house, dating from the 15th century, was the birthplace of the Egyptologist J. F. Champollion. The church of St. Sauveur, once belonging to the abbey of Figeac, is 12th century restored. Notre-Dame du Puy belongs to the 12th and 13th centuries. The altar-screen is a fine example of carved woodwork of the end of the 17th century. Of the four obelisks which used to mark the limits of the authority of the abbots of Figeac, those to the south and the west of the town remain. Figeac is the seat of a subprefect and has a communal college. Trade is in cattle, leather, wool, plums, chestnuts, walnuts and grain, and there are zinc mines in the neighbourhood.

FIGUEIRA DA FOZ, a seaport of central Portugal, in the district of Coimbra, at the terminus of the Lisbon-Figueira and Guarda-Figueira railways. Pop. (1920) 6,787. Figueira da Foz is an important fishing-station, and one of the headquarters of the coasting trade in grain, fruit, wine, olive oil, cork and coal; but owing to the bar at the mouth of the Mondego large ships cannot enter. Glass is manufactured, and the city attracts many visitors by its excellent climate and sea-bathing. A residential suburb, the Bairro Novo, exists chiefly for their accommodation, to the north-west of the old town. Figueira is connected by a tramway running 4 m. N.W. with Buarcos (pop. 5,345) and with the coal-mines of Cape Mondego. Figueira da Foz received the title and privileges of a city in 1882.

FIGUERAS, a town of north-eastern Spain, province of Gerona, 14 m. S. of the French frontier, on the Barcelona-Perpignan railway. Pop. (1920) 13,192. Figueras is built at the foot of the Pyrenees, on the N. edge of El Ampurdán, a fertile and well-irrigated plain, which produces grain, fruit and forage crops, and derives its name from the seaport of Ampurias, the ancient Emporiae. The town, which is modern and rather dull, with leather, cork, glass, iron and other factories, is chiefly remarkable for the castle of San Fernando, built by Ferdinand VI. (1746-1759), on a hill 1 m. N.W. This irregular, pentagonal structure, with accommodation for 10,000 men and 500 horses, is still a key to the frontier owing to its position and rocky approach. In 1794 Figueras was surrendered to the French, but it was regained in 1795. During the Peninsular War it was taken by the French in 1808, recaptured by the Spaniards in 1811, and retaken by the French in the same year. In 1823, after a long defence, it was once more captured by the French.

FIGUEROA, FRANCISCO DE (1536-1617?), Spanish poet, of whose life little is known, was born at Alcalá. Although Figueroa ordered that his poems should be burnt at his death, the order does not seem to have been carried out for Luis Tri baldos de Toledo in 1625 edited over 60 of Figueroa's poems which exhibit his mastery over blank verse and his inclination to the pastoral tradition. A facsimile of this edition was published by A. M. Huntingdon (1903).

See his *Poetas*, edit. A. de Cortes in "Bib. de Autores Esp." vol. xlii. (1857); *Poésies inédites de Figueroa*, edit. R. Foulché-Delbosc in *Revue Hispanique*, vol. xxv. (1911); *Varias composiciones inéditas*, edit. A. Lacalle Fernandez in *Revista crítica hispano-americana* (1919). See also J. Fitzmaurice-Kelly, *A New Hist. of Span. Literature* (1926).

FIGULUS, PUBLIUS NIGIDIUS (c. 98-45 B.C.), Roman savant, next to Varro the most learned Roman of the age. He was a friend of Cicero, to whom he gave his support at the time of the Catilinarian conspiracy (Plutarch, *Cicero*, 20; Cicero, *Pro. Sulla*, xiv. 42). In 58 he was praetor, sided with Pompey in the Civil War, and after his defeat was banished by Caesar, and died in exile. According to Cicero (*Timaeus*, i.), Figulus tried to revive the doctrines of Pythagoreanism, together with mathematics, astronomy and astrology, and even magic. Suetonius (Aug. 94) and Apuleius (Apol. 42) tell of his supernatural powers. Jerome (the authority for the date of his death) calls him *Pythagoricus et magus*. The indifference of the Romans to such abstruse and mystical subjects caused his works to be soon forgotten. They included *De diis*, an examination of cults and ceremonials; treatises on divination and dreams; on the sphere, the winds and animals. His *Commentarii grammatici* in at least 29 books was an ill-arranged collection of linguistic, grammatical and antiquarian notes. He paid especial attention to orthography, and sought to differentiate the meanings of cases of like ending by distinctive

marks. In etymology he tried to find a Roman explanation of words (according to him *frater* was=*fere alter*). Quintilian (*Instit. orat.* xi. 3. 143) speaks of a rhetorical treatise *De gestu* by him.

See Cicero, *Ad. Fam.* iv. 13; scholiast on Lucan I, 639; several references in Aulus Gellius; Teuffel, *Hist. of Roman Literature*, 170; M. Hertz, *De N. F. studiis atque operibus* (1845); *Quaestiones Nigidianae* (1890), and edition of the fragments (1889) by A. Swoboda.

FIGURATE NUMBERS. The early Greek mathematicians found that if groups of dots were used to represent numbers, they could be arranged so as to form geometric figures, examples of which are as follows:—

Of these, the first represents a triangular number; there being 10 dots, 10 is a triangular number. It is also seen that 3 and 6 are triangular numbers. The second figure is a square, and from it we see that 4, 9 and 16 are square numbers. From the third we see that 12 is a pentagonal number. The triangular numbers may be represented by $\frac{1}{2}n(n+1)$, where n is any positive integer. The square numbers are represented algebraically by n^2 , and the pentagonal numbers by $\frac{1}{2}n(n+3)$. The Greeks also considered oblong (heteromecic) numbers, the sides (or factors) of which differ by unity. Thus, 3×4 , 4×5 , . . . are oblong numbers. There were also prolate (promecic) numbers, the factors differing by two or more, as in the case of 2×5 ; but these were often included under oblong numbers. Besides various other types of plane numbers there are solid numbers. For example, 8 is a cubic number, and 5 is a pyramidal one. Numbers which are related to geometric figures in such ways are called *figurate numbers* or *figured numbers*. Plane figurate numbers are also called *polygonal numbers*, the solid figurate numbers being designated as *polyhedral*. The theory probably goes back to Pythagoras (c. 540 B.C.). Such numbers were studied and described by Nicomachus (c. 100), Theon of Smyrna (c. 125), Boethius (c. 510) and many later writers.

FIGURED BASS (also known as THOROUGH-BASS, GENERAL BASS and BASSO CONTINUO) is a kind of musical shorthand, whereby the harmonies of a composition are indicated by means of figures above or below the bass part, instead of in the ordinary notation. It came into existence early in the 17th century in Italy, being introduced in the first place for the use of the organist or cembalist accompanying a choral composition, and thereafter was very widely and generally employed for a long period, but nowadays it is retained in use only in harmony text-books and similar technical works. The principle of the system is quite simple, the figures indicating the interval of the note to be played, reckoning from the bass upwards. Thus a 3 represents a third, a 5 a fifth, a

6 a sixth, and so on, e.g., 5, 6, 5 and the like, chromatic signs being

added when necessary to indicate the inflection of a given interval, e.g., $\sharp 6$, $\flat 9$, $\sharp 4$. Much skill and taste were none the less required for the proper interpretation of a figured bass, more especially as in course of time the signs used were still further abbreviated and simplified, leaving more and more to the knowledge and understanding of the performer, who was required further, not merely to provide the bare harmonies indicated, but to place and connect them in accordance with the laws of correct part-writing, to embellish them with runs, ornaments and so on, and generally to provide, on the strength of the mere indication of the essential harmonies, a complete and satisfying accompaniment.

FIGUREHEAD, an ornamental figure placed under the bowsprit of a sailing ship. It took the form of a full-length figure or scroll handsomely carved and embellished—symbolical of the ship it represented. In ancient times figureheads were placed on the prows of war galleys.

FIJI, a British colony consisting of an archipelago in the Pacific Ocean, the most important in Polynesia, between 15° and 20° S., and on and about the meridian of 180°. The proper name is Viti as in the name of the principal island. The islands number about 250, of which some 80 are inhabited. The total land area is 7,435 sq.m. (thus roughly equalling that of Wales), and the population was estimated (1926), 171,644. The principal island is Viti Levu, 98 m. in length (east to west) and 67 in extreme breadth, with an area of 4,112 sq.m. Forty miles north-east lies Vanua Levu, measuring 117 by 30 m., with an area of 2,432 sq.m. Close off the south-eastern shore of Vanua Levu is Taviani, 26 m. in length by 10 m. in breadth; Kandavu or Kadavu, 36 m. long and very narrow, is 41 m. S. of Viti Levu, and the three other main islands, lying east of Viti Levu in the Koro Sea, are Koro, Ngau or Gau and Ovalau. South-east from Vanua Levu a loop of islets extends nearly to 20° S., enclosing the Koro Sea. North-west of Viti Levu lies another chain, the Yasawa or western group; and, finally, the colony includes the island of Rotumah (*q.v.*), 300 m. N.W. by N. of Vanua Levu.

The formation of the larger islands is volcanic, their surface rugged, their vegetation luxuriant, and their appearance very beautiful; their hills often rise above 3,000 ft., and, in the case of a few summits, above 4,000, and they contrast strongly with the low coral formation of the smaller members of the group. There is not much level country, except in the coral islets, and certain rich tracts along the coasts of the two large islands, especially near the mouths of the rivers. The large islands have a considerable extent of undulating country, dry and open on their lee sides. Streams and rivers are abundant, the latter very large in proportion to the size of the islands, affording a waterway to the rich districts along their banks. The Rewa, debouching through a wide delta at the south-east of Viti Levu, is navigable for small vessels for 40 m. The Dreketi is the chief stream of Vanua Levu.

With few exceptions the islands are surrounded by barriers of coral, broken by openings opposite the mouths of streams. Viti Levu is the most important island not only from its size, but from its fertility, variety of surface, and population, which is over one-third of that of the whole group. The town of Suva lies on an excellent harbour at the south-east of the island, and has been the capital of the colony since 1882, containing the government buildings and other offices. On the eastern shore of Ovalau, an island which contains in a small area a remarkable series of gorge-like valleys between commanding hills, is the town of Levuka, the capital until 1882. The chief islands on the west of the chain enclosing the Koro Sea are Koro, Ngau, Moala and Totoya, all productive, affording good anchorage, elevated and picturesque. The eastern islands of the chain are smaller and more numerous, Vanua Batevu (one of the Exploring Group) being a centre of trade. Among others, Mago is remarkable for a subterranean outlet of the waters of the fertile valley in its midst. For the geology, fauna and flora, economics and administration, etc., of Fiji, see comprehensive article PACIFIC ISLANDS.

PEOPLE

The Fijians are a mixed people of Melanesian (Papuan) and Polynesian (Tongan and Samoan) elements. They occupy the extreme east limits of Papuan territory and are usually classified as Melanesians. Their dark colour and crisp hair, which is bleached with lime and worn in an elaborately trained mop, combine with the handsome features and well proportioned limbs of the Polynesians. The chiefs are fairer and of a less negroid type than the people. This negroid type is especially marked on the west coasts, and in the interior of Viti Levu. They wear a minimum of covering, are strictly decent and more moral than the Polynesians. They are cleanly and particular about their personal appearance, care little for ornament, and only the women are tattooed. A partial circumcision is practised. The status of the women is

also somewhat better, those of the upper class having considerable freedom and influence. They are skilful cultivators and good boat-builders, the carpenters being an hereditary caste; there are also tribes of fishermen and sailors; their mats, baskets, nets, cordage and other fabrics are substantial and tasteful; their pottery, made by women, is superior to any other in the South Seas.

The Fijians were formerly notorious for cannibalism, which may have had its origin in religion, but long before the first contact with Europeans had degenerated into gluttony. The Fijian's chief table luxury was human flesh, euphemistically called "long pig," and to satisfy his appetite he would sacrifice even friends and relatives. Human sacrifices were of daily occurrence. On a chief's death wives and slaves were buried alive with him. When building a chief's house a slave was buried alive in the hole dug for each foundation post. At the launching of a war-canoe living men were tied hand and foot between two plantain stems making a human ladder over which the vessel was pushed down into the water. The people willingly met their deaths. Affection and a firm belief in a future state, in which the exact condition of the dying is continued, are the Fijians' own explanations of the custom, once universal, of killing sick or aged relatives. Cross cousin marriage was practised in parts and there are many features of note in the customs of the hill tribes indicating a strong Melanesian element. Their code of social etiquette is minute and elaborate, and the graduations of rank well marked. These are (1) chiefs, greater and lesser; (2) priests; (3) *Mata ni Vanua* (lit., eyes of the land), employees, messengers or counsellors; (4) distinguished warriors of low birth; (5) common people; (6) slaves.

The family is the unit of society. The families are grouped in townships or otherwise (*gali*) under the lesser chiefs, who again owe allegiance to the supreme chief of the *matanitu* or tribe. The chiefs excel the people in physique, skill, intellect and acquirements of all sorts; and the reverence felt for them was very great and of a religious character.

All that a man had belonged to his chief. On the other hand, the chief's property practically belonged to his people, and they were as ready to give as to take. In a time of famine, a chief would declare the contents of the plantations to be common property. The system of service-tenures (*lala*) on which their social and political fabric mainly depended, allowed the chief to call for the labour of any district, and to employ it in planting, house or canoe-building, supplying food on the occasion of another chief's visit, etc. This power was often used with much discernment.

An allied custom, *solevu*, enabled a district in want of any particular article to call on its neighbours to supply it, giving labour or something else in exchange. Although, then, the chief is lord of the soil, the inferior chiefs and individual families have equally distinct rights in it, subject to payment of certain dues; and the idea of permanent alienation of land by purchase was never perhaps clearly realized. By the custom of *vasu* (lit. nephew) the son of a chief by a woman of rank had almost unlimited rights over the property of his mother's brother or if a chief's nephew over his uncle's female subjects. In time of war the chief claimed absolute control over life and property. Warfare was carried on with many formalities, and considerable skill was shown in the fortifications. There were well-defined degrees of dependence among the different tribes or districts: the first of these, *bati*, is an alliance between two nearly equal tribes, but

BY COURTESY OF E. GALLOWAY

A WARRIOR OF THE FIJI ISLANDS IN DANCE COSTUME AT SUVA

The Fijians resemble the Polynesians in stature and proportions, but in colouring and other minor respects they are entirely like the Melanesians

implying a sort of inferiority on one side, acknowledged by military service; the second, *qali*, implies greater subjection, and payment of tribute.

The religion of the Fijians was a sort of ancestor-worship, had much in common with the creeds of Polynesia, and included a belief in a future existence. There were two classes of gods—the first immortal, of whom Ndengei is the greatest, said to exist eternally in the form of a serpent, but troubling himself little with human or other affairs, and the others had usually only a local recognition. The second rank (who, though far above mortals, are subject to their passions, and even to death) comprised the spirits of chiefs, heroes and other ancestors. The gods entered and spoke through their priests, who thus pronounced on the issue of every enterprise, but they were not represented by idols; certain groves and trees were held sacred, and stones which suggest phallic associations. The priesthood usually was hereditary, and their influence great, and they had generally a good understanding with the chief. The institution of Tabu existed in full force. The *mburé* or temple was also the council chamber and place of assemblage for various purposes. The square house with an occasional rounded variant is in the hill area associated with a Secret Society—the Nanga.

The weapons of the Fijians are spears, slings, throwing clubs and bows and arrows. Their houses, of which the framework is timber and the rest lattice and thatch, are ingeniously constructed, tastefully ornamented, and are furnished with mats, mosquito-curtains, baskets, fans, nets and cooking and other utensils. Their canoes, sometimes more than 100 ft. long, are well built. Ever excellent agriculturists, their implements were formerly digging sticks and hoes of turtlebone or flat oyster-shells. In irrigation they showed skill, draining their fields with built watercourses and bamboo pipes. Tobacco, maize, sweet potatoes, yams, kava, taro, beans and pumpkins, are the principal crops.

Fijians have various games, and dancing, story-telling and songs are especially popular. Their poetry has well-defined metres, and a sort of rhyme. Their music is rude, and is said to be always in the major key. For their feasts preparations are sometimes made months in advance. Mourning is expressed by fasting, by shaving the head and face, or by cutting off the little finger. This last is sometimes done at the death of a rich man in the hope that his family will reward the compliment; sometimes it is done vicariously, as when one chief cuts off the little finger of his dependent in regret or in atonement for the death of another. See W. H. R. Rivers, *History of Melanesian Society* (1914); A. B. Brewster, *Hill Tribes of Fiji* (1922).

HISTORY

A few islands in the north-east of the group were first seen by Abel Tasman in 1643. The southernmost of the group, Turtle island, was discovered by Cook in 1773. Lieut. Bligh, approaching them in the launch of the "Bounty" (see "BOUNTY," MUTINY OF THE) 1789, had a hostile encounter with natives. In 1827 Dumont d'Urville in the "Astrolabe" surveyed them more accurately, but the first thorough survey was that of the United States exploring expedition in 1840. Up to this time, owing to the evil reputation of the islanders, European intercourse was very limited. The labours of the Wesleyan missionaries, however, who came from Tonga in 1835, must always have a prominent place in any history of Fiji.

About 1804 some escaped convicts from Australia and runaway sailors established themselves around the east part of Viti Levu, and by lending their services to the neighbouring chiefs probably led to their preponderance over the rest of the group. Na Ulivau, chief of the small island of Mbau, established before his death in 1829 a sort of supremacy, which was extended by his brother Tanoa, and by Tanoa's son Thakombau, a ruler of considerable capacity.

British Annexation.—However, attacks by the Tongans and financial troubles, including a claim of £9,000 by the United States for alleged injuries to their consul, reduced Thakombau to great difficulties. In 1859 he in vain made a conditional offer to cede the sovereignty to Great Britain, but in 1874, after years of

deeper complications, she accepted the unconditional cession then offered. It had besides long been thought desirable to possess a station on the route between Australia and Panama; it was also felt that the Polynesian labour traffic, the abuses in which had caused much indignation, could only be effectually regulated from a point contiguous to the recruiting field, and the locality where that labour was extensively employed. To this end the governor of Fiji was also created "high commissioner for the western Pacific." Rotumah (*q.v.*) was annexed in 1881.

At the time of the British annexation the islands were suffering from commercial depression, following a fall in the price of cotton after the American Civil War. Coffee, tea, cinchona and sugar were tried in turn, with limited success. The coffee was attacked by the leaf disease; the tea could not compete with that grown by the cheap labour of the East; the sugar machinery was too antiquated to withstand the fall in prices consequent on the European sugar bounties. In 1878 the first coolies were imported from India and the cultivation of sugar began to pass into the hands of large companies working with modern machinery. With the introduction of coolies the Fijians began to fall behind in the development of their country. Many of the coolies chose to remain in the colony after the termination of their indentures, and began to displace the European country traders. With a regular and plentiful supply of Indian coolies, the recruiting of *kanaka* labourers practically ceased.

Recent Progress.—The settlement of European land claims, and the measures taken for the protection of native institutions, caused lively dissatisfaction among the colonists, who laid the blame of the commercial depression at the door of the government; but with returning prosperity this feeling began to disappear. In 1900 the government of New Zealand made overtures to absorb Fiji. The Aborigines Society protested to the colonial office, and the imperial Government refused to sanction the proposal.

The constitution, regulated by Letters Patent of Jan. 31, 1914, as amended in 1916, provides for a legislative council consisting of the governor, some 14 nominated and six elected members, besides three Indian and three native representatives. Mission schools for Fijians have existed for nearly a century. In 1916 an official education department was created. In 1926 an education commission published a Report containing recommendations for increased facilities for native and Indian education.

FILAMENT is the cathode in one of the common types of a vacuum tube for radio receiving sets. The filament may be the source of the electron (*q.v.*) emission which constitutes the current flowing through the vacuous space.

FILANGIERI, CARLO (1784-1867), prince of Satriano, Neapolitan soldier and statesman, was the son of Gaetano Filangieri (1752-1788), a celebrated philosopher and jurist. At the age of fifteen he was admitted to the Military academy at Paris. After serving in the French campaign of 1803-05 he returned to Naples as captain on Masséna's staff to fight the Bourbons and the Austrians in 1806, and subsequently went to Spain, where he followed Jerome Bonaparte in his retreat from Madrid. In consequence of a fatal duel he was sent back to Naples; there he served under Joachim Murat with the rank of general. He fought against the Anglo-Sicilian forces in Calabria and at Messina, and against Eugène Beauharnais, and later in the campaign against Austria, and was severely wounded at the battle of the Panaro (1815). On the restoration of the Bourbon king, Ferdinand

IV. (I.), Filangieri retained his rank and command, but found the army utterly disorganized and impregnated with Carbonarism. In the disturbances of 1820 he adhered to the Constitutionalist party, and fought under General Pepe (*q.v.*) against the Austrians. On the re-establishment of the autocracy he was dismissed from the service, and retired to Calabria where he had inherited the princely title and estates of Satriano.

In 1831 he was recalled by Ferdinand II. and entrusted with various military reforms. On the outbreak of the troubles of 1848 Filangieri advised the king to grant the constitution, which he did in Feb. 1848, but when the Sicilians formally seceded from the Neapolitan kingdom Filangieri was given the command of an armed force with which to reduce the island to obedience. He reconquered Sicily, and remained there as governor until 1855, when he retired into private life, as he could not carry out the reforms he desired owing to the hostility of Giovanni Cassisi, the minister for Sicily. On the death of Ferdinand II. (May 22, 1859) the new king Francis II. appointed Filangieri premier and minister of war. He promoted good relations with France, then fighting with Piedmont against the Austrians in Lombardy, and urged an alliance with Piedmont and a constitution as the only means of saving the dynasty. These proposals being rejected, Filangieri resigned office. After the downfall of the Bourbons Filangieri went into exile for some time. Although he adhered to the new government he refused to accept any dignity at its hands, and died at his villa of San Giorgio a Cremano near Naples on Oct. 9, 1867.

His biography has been written by his daughter Teresa Filangieri Fieschi-Ravaschieri, *Il Generale Carlo Filangieri* (Milan, 1902), an interesting, although somewhat too laudatory volume based on the general's own unpublished memoirs; for the Sicilian expedition see V. Finocchiaro, *La Rivoluzione siciliana del 1848-49* (Catania, 1906, with bibliography), in which Filangieri is bitterly attacked; see also under NAPLES; FERDINAND IV.; FRANCIS I.; FERDINAND II.; FRANCIS II.

FILANGIERI, GAETANO (1752-1788), Italian lawyer, was born at Naples on Aug. 18, 1752, and died at Vico Equense on July 21, 1788. He wrote *La Scienza della legislazione* (vols. i. and ii., 1780; vol. iii., 1783; vols. iv.-vi., 1785), a book which had great influence throughout Europe. Filangieri was an ardent reformer, who desired to sweep away those mediaeval institutions which hampered production and national well-being. The third volume, relating to criminal jurisprudence, was placed on the Index.

The best edition of the *Scienza* is that by Villari (3 vols., 1864-76); the book was translated into most of the European languages (Eng. trans. by R. Clayton, *The Science of Legislation*, 1806).

FILARIASIS, the name of a disease due to the nematode *Filaria sanguinis hominis*, of which two varieties are known *nocturna* and *diurna*. A milky appearance of the urine, due to the presence of a substance like chyle, which forms a clot, had been observed in tropical and subtropical countries; and it was proved that this condition is uniformly associated with the presence in the blood of microscopic eel-like worms, the embryo forms of a *Filaria* (see NEMATODA). Sometimes the discharge of lymph takes place from ulcers on the surface of the body, or there is naevoid elephantiasis of the scrotum, or lymph-scrotum. More or less of blood may occur along with the chylous fluid in the urine. Both the chyluria and the presence of filariae in the blood are curiously intermittent; with the nocturnal variety of parasite possibly not a single filaria is to be seen during the daytime, while they swarm in the blood at night. This alternation may be inverted by causing the patient to sit up all night and sleep through the day.

Sir P. Manson proved that mosquitoes imbibe the embryo filariae from the blood of man; and that many of these reach full development within the mosquito, acquiring their freedom when the latter resorts to water, where it dies after depositing its eggs. Mosquitoes are thus the intermediate host of the filariae, and their introduction into the human body is through the medium of water (see PARASITIC DISEASES).

FILBERT, the name generally given to the oblong nuts of certain Old World species of hazel (*q.v.*) chiefly *Corylus Avellana* and *C. maxima*. The round nuts of these species are often called cob-nuts. Numerous varieties are extensively cultivated in the

Old World, the large nuts of the better kinds forming an important article of commerce, the imports of which into the United States in 1926 amounted to \$2,954,000. Excellent varieties are now grown successfully in the States of Oregon and Washington. The plants are trained in tree form, with a single trunk, and become as large as medium-sized apple trees. In the Pacific North-west the trees should be planted about 25 ft. apart each way. In the Eastern States these varieties and seedlings of them are grown in bush form. The Constantinople hazel (*C. Colurna*) is a large forest tree producing small nuts which are used for seedlings for stocks on which to bud or graft the choice European varieties. The filbert is also propagated by layering the branches to form roots and by digging the suckers or sprouts from the roots. Seedlings are easily grown from nuts stratified over winter, an inch or two deep in soil and planted in the spring. (C. P. C.)

FILCHNER, WILHELM (1877-), German traveller, was born at Munich on Sept. 13, 1877. He was educated at the Prussian War academy, entered the army and was for some time attached to the general staff. He travelled in the Pamir region in 1900; was head of the German China-Tibet expedition of 1903; conducted the German Antarctic expedition of 1910-12, which discovered the south-western continuation of Coats Land; and in 1913 made arrangements to accompany Amundsen on his polar expedition the following year. The outbreak of the World War, however, recalled him to military duty. In Dec. 1925 he went on an expedition to Tibet, from which he returned in May 1928, after having made complete maps of the region traversed and established 157 magnetic stations.

His works include accounts of his travels, among the most important being *Wissenschaftliche Ergebnisse der Expeditionen Filchner nach China und Tibet* (11 vols. and four large maps, 1907-14).

FILDES, SIR LUKE (1844-1927), English painter, was born at Liverpool, and trained in the South Kensington and Royal Academy schools. His "The Casual Ward" (1874), is at Royal Holloway college; "The Doctor" (1891), is in the National Gallery of British Art (Tate Gallery), London. He painted a number of pictures of Venetian life and many notable portraits, among them the coronation portraits of King Edward VII. and Queen Alexandra and of King George V. He was elected A.R.A. in 1879, and R.A. in 1887; was knighted in 1906, and made K.C.V.O. in 1918.

See David Croal Thomson, *The Life and Work of Luke Fildes, R.A.* (1895).

FILE. Originally a string or thread (through the Fr. *fil* and *file*, from Lat. *filum*, a thread); hence used of a device, originally a cord, wire or spike on which letters, receipts, papers, etc., may be strung for convenient reference. The term has been extended to embrace various methods for the preservation of papers in a particular order, such as expanding books, cabinets, and ingenious improvements on the simple wire file which enable any single document to be readily found and withdrawn without removing the whole series (see OFFICE APPLIANCES). From the devices used for filing the word is transferred to the documents filed, and thus is used of a catalogue, list, or collection of papers.

File is also employed to denote a row of persons or objects arranged one behind the other. In military usage a "file" is the opposite of a "rank," that is, it is composed of a (variable) number of men aligned from front to rear one behind the other, while a rank contains a number of men aligned from right to left abreast. Up to about 1600 infantry were often drawn up 16 deep, one front rank man and the 15 "coverers" forming a file. The number of ranks and, therefore, of men in the file diminished first to ten (1600), then to six (1630), then to three (1700), and finally to two (about 1808 in the British army, 1888 in the German). This formation is still retained for parade purposes in the British Army, extended order with wide intervals between men being used in the field, but most foreign armies have now adopted even for parade purposes a formation based on single file (see ORDER). In the 17th century a file formed a small command under the "file leader," the whole of the front rank consisting therefore of old soldiers or non-commissioned officers. In the above it is to be understood that the men are facing to the front

or rear. If they are turned to the right or left so that the company now stands two men broad and fifty deep, it is spoken of as being "in file." From this come such phrases as "single file" or "Indian file" (one man leading and the rest following singly behind him). The use of verbs "to file" and "to defile," implying the passage from fighting to marching formation, is to be derived from this rather than from the resemblance of a marching column to a long flexible thread, for in the days when the word was first used the infantry company whether in battle or on the march was a solid rectangle of men, a file often containing even more men than a rank.

File is also the name of a common tool used for abrading or smoothing; see FILE MANUFACTURE. In this sense, the word used has a different derivation, from O.E. *fēol*, from an Indo-European root meaning to mark or scratch.

FILE-FISH or TRIGGER-FISH, the names given to fishes of the genus *Balistes* (and *Monacanthus*) of the family *Balistidae* and sub-order *Balistiformes*, inhabiting all tropical and subtropical seas. The body is compressed and not covered with ordinary scales, but with small juxtaposed scutes. The first of the three dorsal spines is very strong, roughened in front like a file and hollowed out behind to receive the second much smaller spine, which, besides, has a projection in front, at its base, fitting into a notch of the first. Thus these two spines can only be raised or depressed simultaneously, in such a manner that the first cannot be forced down unless the second, which has been compared to a trigger, has been previously depressed. Both jaws are armed with eight strong incisor-like and sometimes pointed teeth, by which these fishes are enabled to break off pieces of madrepores and other corals, on which they feed and to chisel a hole into the hard shells of Mollusca, in order to extract the soft parts. In this way they do much injury to pearl-fisheries. *Monacanthus* has only one dorsal spine and a velvety skin. Some 30 different species are known of *Balistes* and about 50 of *Monacanthus*.

FILELFO, FRANCESCO or PHILELPHUS (1398–1481), Italian humanist, was born on July 25, 1398, at Tolentino, in the March of Ancona. He studied at Padua and in 1417 was invited to teach eloquence and moral philosophy at Venice. In 1419 he became secretary to the Venetian consul-general (*baylo*) in Constantinople. This appointment gave him the opportunity of acquiring the Greek language and of collecting Greek mss. He studied under John Chrysoloras, whose daughter he married, and on whose recommendation he was employed in several diplomatic missions by the emperor John Palaeologus. In 1427 he returned to Venice, to find that the city had almost been emptied by the plague, and that his scholars would be few. He removed to Bologna, and then to Florence. There he lectured to large audiences of young and old on the principal Greek and Latin authors, and on Sundays he explained Dante to the people in the Duomo. He also translated portions of Aristotle, Plutarch, Xenophon and Lysias from the Greek. His temper was arrogant, and when Cosimo de' Medici was exiled by the Albizzi party in 1433, he urged the signoria of Florence to pronounce upon him the sentence of death. On Cosimo's return to Florence, Filelfo's position in that city was no longer tenable, and he moved to Siena, and finally (1440) to Milan, where he found a patron in the duke, Filippo Maria Visconti.

On the death of Visconti, Filelfo, after a short hesitation, transferred his allegiance to Francesco Sforza, the new duke of Milan; and in order to curry favour with this parvenu, he began his ponderous epic, the *Sforziad*, of which 12,800 lines were written, but which was never published. When Francesco Sforza died, Filelfo turned his thoughts towards Rome. He was now an old man of 77, recognized as the greatest of Italian humanists. He reached Rome in 1475, but within a year fell into disgrace with pope Sixtus IV., and returned to Milan. Lorenzo de' Medici invited him to teach Greek at Florence. He died two weeks after his arrival, on July 31, 1481.

Filelfo deserves commemoration among the greatest humanists of the Italian Renaissance, for his energy and untiring activity. He had a large share in amassing and cataloguing the fragments rescued from the wrecks of Greece and Rome. In the work of

collection and instruction Filelfo excelled, passing rapidly from place to place, stirring up the zeal for learning by the passion of his own enthusiastic temperament, and acting as a pioneer for men like Poliziano and Erasmus.

See Carlo de' Rosmini, *Vita di Filelfo* (3 vols., Milan, 1808); Benaducci, *Contributo alla biografia di Francesco Filelfo* (1902); J. A. Symonds, *Renaissance in Italy* (1877). A complete edition of Filelfo's Greek letters (based on the Codex Trevulzianus) was published for the first time, with French translation, notes and commentaries, by E. Legrand in 1892 at Paris (C. xii. of *Publications de l'école des lang. orient.*). For further references, especially to monographs, etc., on Filelfo's life and work, see Ulysse Chevalier, *Répertoire des sources hist., bio-bibliographie* (1905), s.v. *Philelphe, François*.

FILE MANUFACTURE. Like every other steel tool of modern manufacture, the file has been improved greatly in quality by metallurgical and engineering science. The industry has been more especially developed in Sheffield and the United States, but it is also carried on in Switzerland, Germany, Sweden, France and Italy.

There is a great variety of patterns, sizes and cuts of files. They are made from bars whose cross-sectional area may be either round, square, flat, triangular (three-square), half-round—i.e., with one face flat, the back of the file being curved—and a large number of other shapes made for special purposes. Each of these shapes may be made in various lengths, from the tiny watch-makers' and jewellers' file, to the heavy files used by the engineer—20 inches and upwards in length. The sawmaker uses a "three-square" file, cut on the edges for sharpening hand-saws, but for the bandsaw the edge of the file must be thicker and rounded,

to minimize the risk of breaking the band-saw tooth. The flat file with one or two rounded edges is used generally for sharpening circular saw teeth. The locksmith uses a thin flat file varying in thickness, the jeweller has standard shapes drawn to a very fine point, while the dentist uses a very fine pointed, solid-handled, half-round file. The "rasp," with its large, sharp, single teeth is used for wood, hot iron and soft metal; different varieties are the shoe-maker's rasp, the horse rasp for farriers and rasps for cabinet-makers, workers in bone and other similar materials. Each shape and size of file is made in a variety of cuts, the different cuts are known as:—rough, middle, common or bastard, second, smooth, dead-smooth and double-dead-smooth.

Processes of Production.—The metal used for the manufacture of files must be hard enough to cut steel, and at the same time of a quality to give maximum durability under rough treatment; the file teeth must be hard without being brittle. The steel used for the purpose is, therefore, of very good quality with high carbon content.

Such a steel, however, in its normal condition is a hard and difficult one to manipulate. The six chief processes in the production of the file consist of:—forging, annealing, grinding, cutting, hardening and scouring.

Forging and Annealing.—The steel is first received from the rolling mill where it has been rolled to the desired section, and is cut into suitable lengths. These are then placed, a few at a time, in a furnace and heated to a bright red heat. They are then withdrawn separately and hammered under a machine hammer. The first operation of the hammer is to form the "tang" or sharp handle-end of the file, which is later to be inserted into the handle. The hammer is provided with shaping tools or dies to suit the special section of steel to be dealt with. The file is then returned to the furnace and the remaining part of the forging operation is completed. The forged file is known as a "blank." The power-hammer employed consists of a top tool or "tup" and a solid base, into which is fixed the shaping die or tool. These hammers are

TYPES OF FILES
(A) Single out file, (B) double cut file and (C) rasp

designed to deliver from 250 to 500 blows per minute according to the size of the file required. The "blanks" from the hammer must now be brought to a ductile and uniform condition for the purpose of cutting the teeth. They are, therefore, put into an annealing furnace and heated gradually to the desired temperature. They are held at that heat, and then cooled. This treatment produces a change in the physical condition of the steel, removing all internal strains and rendering the material suitable for the subsequent operation of the cutting of the teeth.

Grinding.—The object of grinding is to produce a smooth, even surface on the face of the blank, and to remove the scale from the surface to be cut. This operation is largely carried out by machinery. A grinding wheel is mounted in a machine which is made to rotate at a suitable speed, and in addition an oscillating motion is imparted to the axle of the wheel to prevent grooves being worn into the face of the wheel. The files are fixed in a trough in the base of the machine, and are completely covered by water. The trough automatically moves to and fro under the grinding wheel, and provision is made for the grinding wheel to be lowered or raised to grind the files. Special arrangements are made for grinding half-round and round files.

Cutting.—The operation of forming the teeth in files is known as "file-cutting," and is now almost entirely a machine operation. Formerly the operation was performed by hand with flat chisels, and the process became an art in which the skilled file-cutter attained great efficiency. The file-cutting machine is designed to reproduce by mechanical means the processes adopted by the file-cutter, except that the number of cuts per minute made by the machine is enormously greater than is possible by hand. The file blank is placed on a lead bed made to the shape of the file to be cut. The chisel employed for cutting the grooves in the blank has a straight sharp edge and is sufficiently long to overlap the file blank. The edge is ground and shaped to the desired angles, whetted, and the sharp edge rubbed off. The grooves are cut across the face of the blank at an angle to the side of the file, which varies for different materials. Files are made either with a single series of cuts, known as "single-cut" files, or with a double series of cuts, crossing one another, known as "double-cut" files. The single cut files are used for the softer materials such as brass, lead and wood, and the double cut file is the one commonly used in machine shops. The crossing of the face of the file by the two series of cuts placed at different angles with one another, as described, has the effect of breaking up the long rows of single teeth, stretching across the width of the file, into a large number of separate small pointed teeth each presenting its sharpened point to the surface of the work to be cut. (See figure for the single cut file, the double cut file and the rasp.)

Hardening and Scouring.—On the completion of the cutting operation the files undergo a process of hardening. The teeth of the file are first protected from injury by a special plastic covering, and the file is then heated to the desired temperature for high carbon steel files. It is then quenched by dipping into a brine bath out of which it is brought before the centre of the file is cold. Whilst in this condition, that is before complete cooling, the distorted files can be straightened. After hardening, the file is subjected to a process of passing it over a sand-blast jet, through which steam and sand are forced at about 70 lb. pressure. This treatment leaves a perfectly clean surface on the finished file. Files are tested in the works by passing, by hand, a "prover" which consists of a hard piece of steel, over the teeth of the new file, the effect of which must be to leave the teeth undamaged. Further tests of files are made in file-testing machines, which have been designed to measure the amount of material which the file is capable of removing from a standardized test-bar during a given number of strokes of the file, and at a standard pressure upon the file.

Care of the File.—Many files are impaired by being improperly used. A very sharp file, for example, should not be used on an oxidized surface of cast iron, a surface which is itself as hard as the file teeth. A partially worn file should first be used for the purpose, and the new file for finishing the work

only. Care should also be taken to avoid excessive pressure when using a sharp new file. In using a file for cutting, just enough pressure should be put upon it during the forward stroke to make it cut freely, and the file should be slightly lifted from the work during the return stroke. Files should be cleaned after use and put away carefully, not thrown among other metal tools.

(W. R.)

FILEY, an urban district and seaside resort, Buckrose parliamentary division, East Riding of Yorkshire, England, 9½ m. S.E. of Scarborough by the L.N.E. railway, and 7½ m. by road. Pop. (1931), 3,730. It stands upon the slope and summit of the cliffs above Filey bay, which is fringed by a fine sandy beach. The bay stretches from Filey Brigg, formerly called "The File," a narrow and abrupt promontory extending, by dangerous reefs nearly ½ m. out to sea, southwards and south-eastwards to the finer promontory of Flamborough head. Roman remains have been discovered on the cliff north of the town. The church of St. Oswald is a fine cruciform building, with central tower, transitional Norman and Early English in date. It is a coast-guard and life-boat station and has a red fixed light which is seen for 1 mile. Its fisheries are important. Filey is a quiet resort, with pleasant promenades and good golf links; also a small spa, to the north of the town, which has fallen into disuse.

FILIBUSTER, a name originally given to the buccaneers (*q.v.*). The term is probably derived from the Dutch *vry buiter*, freebooter; it was revived in America to designate those adventurers who, after the termination of the war between Mexico and the United States, organized expeditions within the United States to take part in West Indian and Central American revolutions. The modern use of the word denotes one who engages in private warfare against any state. In the United States it is colloquially applied to legislators who practise obstruction.

FILICAJA, VINCENZO DA (1642–1707), Italian poet, was born at Florence on Dec. 30, 1642. He studied under the Jesuits at Florence, and then in the university of Pisa. He then returned to Florence, married Anna Capponi, and devoted himself to literary pursuits. His rhetorical genius was fired by the deliverance of Vienna from the Turks in 1683, and he wrote the canzoni which made him famous. The grand duke of Tuscany, Cosmo III., conferred on him a useful sinecure, and he was named governor of Volterra in 1696. Both there and at Pisa, where he was governor in 1700, he was extremely popular. He passed the close of his life at Florence, was nominated senator, and died in that city on Sept. 24, 1707. Much of his verse was pretentious and artificial, but when he is thoroughly natural and spontaneous—as in the two sonnets "Italia, Italia, o tu cui feo la sorte" and "Dov' è, Italia, il tuo braccio? e a che ti serve"; in the verses "Alla beata Vergine," "Al divino amore"; in the sonnet "Sulla fede nelle disgrazie"—the truth and beauty of thought and language recall the verse of Petrarch.

Complete edition (Venice, 1762); selection, *Poesie e lettere* (Florence, 1864). See G. Caponi, *Vincenzo da Filicaja e le sue opere* (1901).

FILIGREE, jewel work of a delicate kind made with twisted threads usually of gold and silver. Though filigree has become a special branch of jewel work it was originally part of the ordinary work of the jeweller. Signor A. Castellani states, in his *Memoir on the Jewellery of the Ancients* (1861), that the jewellery of the Etruscans and Greeks was made by soldering together and so building up the gold, rather than by chiselling or engraving the material. The art may be said to consist in curling, twisting and plaiting fine, pliable threads of metal, and uniting them at their points of contact with each other, and with the ground, by means of gold or silver solder and borax, by the help of the blow-pipe. Small grains or beads of the same metals are often set in the eyes of volutes, on the junctions or at intervals at which they will set off the wire-work effectively. The more delicate work is generally protected by framework of stouter wire. Brooches, crosses, ear-rings and other personal ornaments of modern filigree are generally surrounded and subdivided by bands of square or flat metal giving consistency to the filling up, which would not otherwise keep its proper shape.

The Egyptian jewellers employed wire, both to lay down on a background and to plait or otherwise arrange *à jour*. But, with the exception of chains, it cannot be said that filigree work was much practised by them. Their strength lay rather in their cloisonné work and their moulded ornaments. Many examples, however, remain of round plaited gold chains of fine wire, such as are still made by the filigree workers of India, and known as Trichinopoli chains. From some of these are hung smaller chains of finer wire with minute fishes and other pendants fastened to them. In ornaments derived from Phoenician sites, such as Cyprus and Sardinia, patterns of gold wire are laid down with great delicacy on a gold ground, but the art was advanced to its highest perfection in the Greek and Etruscan filigree of the 6th to the 3rd century B.C.

It is probable that in India and various parts of central Asia filigree has been worked from the most remote period without any change in the designs. Whether the Asiatic jewellers were influenced by the Greeks settled on that continent, or merely trained under traditions held in common with them, it is certain that the Indian filigree workers retain the same patterns as those of the ancient Greeks, and work them in the same way, down to the present day. Wandering workmen are given so much gold, coined or rough, which is weighed, heated in a pan of charcoal, beaten into wire and then worked in the courtyard or veranda of the employer's house according to the designs of the artist, who weighs the complete work on restoring it and is paid at a specified rate for his labour. Very fine grains or beads and spines of gold, scarcely thicker than coarse hair, projecting from plates of gold, are methods of ornamentation still used.

Passing to later times we may notice in many collections of mediaeval jewel work reliquaries, covers for the gospels, etc., made either in Constantinople from the 6th to the 12th century, or in monasteries in Europe, in which Byzantine goldsmiths' work was studied and imitated. These objects, besides being enriched with precious stones, polished, but not cut into facets, and with enamel, are often decorated with filigree. In the north of Europe the Saxons, Britons and Celts were, from an early period, skilful in several kinds of goldsmiths' work.

The Irish filigree work is more thoughtful in design and more varied in pattern than that of any period or country that could be named. Its highest perfection must be placed in the 10th and 11th centuries. The Royal Irish Academy in Dublin contains a number of reliquaries and personal jewels, of which filigree is the general and most remarkable ornament. The "Tara" brooch has been copied and imitated, and the shape and decoration of it are well known. Instead of fine curls or volutes of gold thread, the Irish filigree is varied by numerous designs in which one thread can be traced through curious knots and complications, which, disposed over large surfaces, balance one another, but always with special varieties and arrangements difficult to trace with the eye. The long thread appears and disappears without breach of continuity, the two ends generally worked into the head and the tail of a serpent or a monster. The reliquary containing the "Bell of St. Patrick" is covered with knotted work in many varieties. A two-handled chalice, called the "Ardagh cup,"

found near Limerick in 1868, is ornamented with work of this kind of extraordinary fineness.

Much of the mediaeval jewel work all over Europe down to the 15th century, on reliquaries, crosses, croziers and other ecclesiastical goldsmiths' work, is set off with bosses and borders of filigree. Filigree work in silver was practised by the Moors of Spain during the middle ages with great skill, and was introduced by them and established all over the peninsula, whence it was carried to the Spanish colonies in America. The Spanish filigree work of the 17th and 18th centuries is of extraordinary complexity (examples in the Victoria and Albert Museum), and silver filigree jewellery of delicate and artistic design is still made in considerable quantities throughout the country. The manufacture spread over the Balearic islands, and among the populations that border the Mediterranean. It is still made all over Italy and in Malta, Albania, the Ionian islands and many other parts of Greece. That of the Greeks is sometimes on a large scale, with several thicknesses of wires alternating with larger and smaller bosses and beads, sometimes set with turquoises, etc., and mounted on convex plates, making rich ornamental headpieces, belts and breast ornaments. Filigree silver buttons of wire-work and small bosses are worn by the peasants in most of the countries that produce this kind of jewellery. Silver filigree brooches and buttons are also made in Denmark, Norway and Sweden. Some very curious filigree work was brought from Abyssinia after the capture of Magdala—arm-guards, slippers, cups, etc., some of which are now in the South Kensington museum. (See also SILVERSMITHS' AND GOLDSMITHS' WORK; JEWELLERY.)

FILING DEVICES: see OFFICE APPLIANCES.

FILIPESCU, NICHOLAS (1862–1916), Rumanian politician, was born at Bucharest and studied in Paris and Geneva. He entered the Chamber of Deputies in 1885 as a member of the Conservative Party, to which his interests, as a rich landowner, attached him. In 1910 he became the leader of the younger Conservatives, but an unfortunate personal feud with Palle Ionescu largely paralysed his activities, and ended in the secession of Ionescu, who formed the new Conservative-Democrat Government. As minister of war in the Carp cabinet of 1910, Filipescu undertook a reorganization of the Rumanian army on a large scale. In 1913 he and Carp, then in the Opposition, were largely responsible by their agitation for Rumania's participation in the Second Balkan War and subsequent acquisition of Silistria. On the outbreak of the World War Filipescu, with his followers, demanded Rumania's armed intervention on the side of the Allies. The result was a split between Filipescu and Marghiloman's Germanophile party, the former joining Take Ionescu's group. He lived to see the triumph of his policy, but not the subsequent débâcle, dying at Bucharest in 1916.

FILLAN, SAINT or FAELAN, the name of the two Scottish saints, of Irish origin, whose lives are of a purely legendary character. The St. Fillan whose feast is kept on June 20 had churches dedicated to him at Ballyheyland, Queen's county, Ireland, and at Loch Earn, Perthshire. The other, who is commemorated on Jan. 9, was specially venerated at Cluain Mavscua, Co. Westmeath, Ireland, and about the 8th or 9th century at Strathfillan, Perthshire, Scotland, where there was an ancient monastery dedicated to him. This monastery became a cell of the abbey of canons regular at Inchaffray, and was supposed to possess the Saint's crozier, the head of which is now deposited in the National museum of the Society of Antiquaries of Scotland.

The legend of the second saint is given in the Bollandist *Acta SS.* (1643), Jan. 9; see also D. O'Hanlon, *Lives of Irish Saints* (Dublin, 1825).

FILLET, a band or ribbon used for tying the hair, the Lat. *viitta*, which was used as a sacrificial emblem, and also worn by vestal virgins, brides and poets. The word is thus applied to anything in the shape of a band or strip, as, in coining, to the metal ribbon from which the blanks are punched. In architecture, a "fillet" is a narrow flat band, sometimes called a "listel," which is used to separate mouldings one from the other, or to terminate a suite of mouldings as at the top of a cornice. In a fluted column the fillet is often employed between the flutes. It is a very im-

portant feature in Gothic work, being frequently worked on large mouldings (*q.v.*); when placed on the front and sides of the moulding of a rib it is termed the "keel and wings" of the rib.

In cooking, "fillet" is used of the "undercut" of a sirloin of beef, or of a thick slice of fish or meat; more particularly of a boned and rolled piece of veal or other meat, tied by a "fillet" or string.

FILLING: see WARP AND WEFT.

FILLMORE, MILLARD (1800–1874), 13th president of the United States of America, came of a family of English stock, which had early settled in New England. His father, Nathaniel, in 1795 made a clearing within the limits of what is now the town of Summerhill, Cayuga county, N.Y., and there Millard Fillmore was born, on Jan. 7, 1800. Until he was 15 he could have acquired only the simplest rudiments of education, and those chiefly from his parents. At that age he was apprenticed to a fuller and clothier, to card wool and to dye and dress the cloth. Two years before the close of his term, with a promissory note for \$30, he bought the remainder of his time from his master, and at the age of 19 began to study law. In 1820 he made his way to Buffalo, then only a village, and supported himself by teaching school and aiding the postmaster while continuing his studies. In 1823 he was admitted to the bar, and began practice at East Aurora, N.Y. Hard study, temperance and integrity gave him a good reputation and moderate success; in 1827 he was made an attorney and in 1829 counsellor of the supreme court of the State. Returning to Buffalo in 1830, he formed in 1832 a partnership with Nathan K. Hall (1810–74), later a member of Congress and postmaster general in his cabinet. Solomon G. Haven (1810–61), member of Congress from 1851 to 1857, joined them in 1836. The firm met with great success.

From 1829 to 1832 Fillmore served in the State assembly, and, in the single term of 1833–35, in the National House of Representatives, coming in as anti-Jackson, or in opposition to the administration. From 1837 to 1843, when he declined further service, he again represented his district in the House, this time as a member of the Whig Party. In Congress he opposed the annexation of Texas as slave territory, was an advocate of internal improvements and a protective tariff, supported J. Q. Adams in maintaining the right of offering anti-slavery petitions, advocated the prohibition by Congress of the slave trade between the States and favoured the exclusion of slavery from the District of Columbia. His speech and tone, however, were moderate on these exciting subjects, and he claimed the right to stand free of pledges, and to adjust his opinions and his course by the development of circumstances. The Whigs having the ascendancy in the 27th Congress, he was made chairman of the House committee on ways and means. Against a strong opposition he carried an appropriation of \$30,000 to Morse's telegraph. In 1844 he was the Whig candidate for the governorship of New York, but was defeated. In Nov. 1847 he was elected controller of the State of New York, and in 1848 he was elected vice president of the United States on the ticket with Zachary Taylor as president. Fillmore presided over the Senate during the exciting debates on the Compromise Measures of 1850.

President Taylor died on July 9, 1850, and on the next day Fillmore took the oath of office as his successor. The cabinet which he called around him contained Daniel Webster, Thomas Corwin and John J. Crittenden. On the death of Webster in 1852, Edward Everett became secretary of State. Unlike Taylor, Fillmore favoured the Compromise Measures, and his signing one of them, the Fugitive Slave law, in spite of the vigorous protests of anti-slavery men, lost him much of his popularity in the North. Commodore Matthew Calbraith Perry's expedition, which opened up diplomatic relations with Japan, occurred during his term. In the autumn of 1852 he was an unsuccessful candidate for nomination for the presidency by the Whig National Convention, and he went out of office on March 4, 1853. In Feb. 1856, while he was travelling abroad, he was nominated for the presidency by the American or Know-Nothing party, and later this nomination was also accepted by the Whigs; but in the ensuing presidential election, the last in which the Know-Nothings and

the Whigs as such took any part, he received the electoral votes of only one State, Maryland. Thereafter he took no public share in political affairs. Fillmore was twice married; in 1826 to Abigail Powers (who died in 1853, leaving him with a son and daughter), and in 1858 to Mrs. Caroline C. McIntosh. He died at Buffalo March 8, 1874, and was buried in Forest Lawn in that city.

In 1907 the Buffalo Historical Society, of which Fillmore was one of the founders and the first president, published the *Millard Fillmore Papers* (vol. x. and xi. of the society's publications; edited by F. H. Severance), containing miscellaneous writings and speeches, and official and private correspondence. Most of his correspondence, however, was destroyed in pursuance of a direction in his son's will. See William E. Griffis, *Millard Fillmore* (Ithaca, N.Y., 1915).

FILM, a thin skin, pellicle or lamina of any material, an opaque layer; a fine cobweb, gossamer or silk thread. Body surface emanations in Epicureanism were films, supposedly perceptible objects. In physics it is a liquid or gaseous coating; botanically, a seed pod partition. Verbally the word means to cover or be covered with film. In photography (*q.v.*) a collodion or gelatin-coated paper or plate, or merely the coating is a film. Popularly, in the United States, it is the sheet or roll of material, such as celluloid, recording a moving picture (see *MOTION PICTURE*) or still camera negative; the finished positive; or a completed cinema production. To "film a scene" is a very common term.

FILMER, SIR ROBERT (d. 1653), English political writer, champion of the "divine right" of kings, was born at East Sutton, Kent, and educated at Trinity college, Cambridge. He was an ardent supporter of the king's party, and his house is said to have been sacked ten times during the Civil War. Filmer held that God gave authority to Adam, an authority inherited by Noah and handed down to his three sons; from the patriarchs, kings and governors derived an absolute authority, founded on divine right. The king was perfectly free from all human control. These views were developed in a series of works of which the most complete, *Patriarcha*, was not published until 1680.

The *Patriarcha* was reprinted (1883) in Morley's Universal Library.

FILMY FERNS, a general name for a family of ferns, the Hymenophyllaceae, with delicate, much-divided leaves and often moss-like growth, comprising the genera *Hymenophyllum* and *Trichomanes*, together comprising some 450 species, natives chiefly of the humid tropics and mainly epiphytic. Two species of *Trichomanes* occur in the south-eastern United States. Various species are in greenhouse cultivation. They require to be kept in close cases in a cool fernery, and the stones and moss amongst which they are grown must be kept continually moist so that the evaporated water condenses on the leaves.

FILON, AUGUSTIN (1841–1916), French man of letters, son of the historian C. A. D. Filon (1800–75), was born in Paris in 1841. His father became professor of history at Douai, and eventually *inspecteur d'académie* in Paris; his principal works were *Histoire comparée de France et de l'Angleterre* (1832), *La Diplomatie française sous Louis XV.* (1843), *Histoire de la démocratie athénienne* (1854). Educated at the École normale, Augustin Filon accompanied the Prince Imperial, as tutor, to England, where he remained for some years. He is the author of *Guy Patin, sa vie, sa correspondance* (1862); *Nos grands-pères* (1887); *Prosper Mérimée* (1894); *Sous la tyrannie* (1900); *Histoire de la littérature anglaise* (1883); *Le Théâtre anglais* (1896); *L'Angleterre d'Edouard VII.* (1911); *Souvenirs et documents* (1912), relating to the Prince Imperial. He died at Croydon, England, on May 13, 1916.

FILTER, ELECTRIC WAVE, a device used in radio sets, usually a selective circuit network, designed to transmit a direct current or alternating current within a continuous band or bands of frequencies. It also attenuates currents of other frequencies. (See *ELECTRICITY* and *BROADCASTING*.)

FILTER-PASSING VIRUSES, organisms small enough to pass through a bacterial filter made of unglazed porcelain or compressed infusorial earth. In these filters the grains of the china clay or infusorial earth used for their manufacture are sufficiently small and uniform to leave interstices, the cross section of which is 0.2 to 0.8 μ in diameter. If a liquid containing microbes whose

smallest diameter exceeds 0.2μ be pressed through the filter, the microbes remain impacted in the smaller crevices. As 0.2μ is also the limit of size of a particle which can be resolved by the best microscopes (*see* MICROSCOPY) when white light is used, filter-passing organisms are either invisible or on the margin of visibility. Hence, most of them have been classed as "ultravisible viruses."

Discovery.—The first discovery, that an ultramicroscopic or filterable virus was the cause of an animal disease, was made by Loeffler in 1898 in the course of some experiments upon foot-and-mouth disease, in which a filter of infusorial earth was used to remove ordinary recognizable bacteria from the diluted contents of the superficial vesicles which are characteristic of this disease. The filtrate was free from any particles visible by the microscope and no bacteria developed in it on cultivation. Nevertheless, injection of this filtrate into animals caused disease. Material removed from the vesicles of the animal so infected and filtered again reproduced the disease in a fresh animal. Similar experiments were carried out through a number of generations of animals, so that there was no doubt that a virus capable of propagation in the animal body was contained in the filtrates. In the next few years the filterability of the virus was established in the case of infectious pleuro-pneumonia of cattle, South African horse-sickness and fowl plague.

Yellow Fever.—The cause of yellow fever has been shown by Noguchi to be a spirochaete which, owing to its thinness and motility, can pass through a bacterial filter.

Human Diseases.—Up to 1927 the virus of about 40 diseases of man and domestic animals had been found to pass through a bacterial filter by reliable observers. The more important of these are the following; foot-and-mouth disease, contagious bovine pleuro-pneumonia, African horse-sickness, fowl plague, yellow fever, cattle plague, sheep-pox, *epithelioma contagiosum* of birds, swine fever, rabies, cow-pox (*vaccinia*), *molluscum contagiosum* of man, equine infectious pernicious anaemia, canine distemper, "blue tongue" of sheep, dengue fever, papataci or sand-fly fever, smallpox, trachoma, poliomyelitis, measles, typhus fever, trench fever, mumps, Rocky Mountain spotted fever and *herpes labialis*.

Influenza.—Recently, Olitzky has succeeded in propagating on special culture media seven varieties of small microbes from the filtrates through a "bacteria proof" filter of washings of the throats of individuals suffering from catarrhal diseases. One of them is credited, on substantial grounds, with being the cause of pandemic influenza (*q.v.*), another is supposed by its discoverer to be responsible for our common colds. The others do not appear to be of pathological significance.

Cancer Research.—There is now reason to suppose that filterable viruses play some part in the origin of cancer (*see* CANCER RESEARCH). When a fragment of a malignant tumour is implanted in the tissues of an animal of the same species it generally grows and ultimately kills the animal. The animal cells of which the cancer is composed are endowed with a faculty for growth, uncontrolled by those factors which determine normal tissue equilibrium. The possibility that this property was due to infection of the cells by a microbe has, in the past, occupied the attention of investigators, but no experimental basis for this view was afforded till 1911, when Peyton Rous described a sarcoma of the fowl which differed from mammalian tumours in that it was transmissible from chicken to chicken by means of a filtrate from a filter which kept back all of the malignant cells (much too large to traverse its pores) and also any bacteria of ordinary dimensions. This filtrate could be dried at a low temperature and the powder retained its activity for years. It had no effect when injected into animals other than chickens, and it always produced the same type of tumour.

As the same result could not be obtained with a filtered extract of other malignant growths, this very important discovery was interpreted to mean that this fowl-sarcoma was a thing apart, although in structure and behaviour it closely resembled the mammalian sarcomata. Subsequently, its discoverer found that two other malignant tumours of fowls possessed similar properties, and quite recently Carrel has recorded the formation of

malignant tumours in fowls following local irritation of the tissues with tar or arsenic, filtrates from which were also infective for chickens. Rous believed that the filterable agent which caused the tumours he studied was, probably, an extremely small microbe, but as he did not succeed in propagating it outside the body its nature remained undetermined. The nature of the infective agent in the filtrate of Rous's tumour has recently been investigated by Gye, who believes he has succeeded in growing it in test tubes in a special medium. The culture has been carried on through several generations of transplantations. By this means the virus has been purified from the other constituents of the original implant. The inoculation of this purified virus alone did not give rise to a tumour, but if mixed with an extract of the fresh tumour, in which the virus has been killed by chemical agents and which alone was innocuous, a tumour occurred. In other words, he holds that the conjunction of two factors, living virus and some non-living chemical substance or substances, is necessary to provoke the cells of the animal to that anarchical development which is characteristic of malignant growth.

Gye's Experiments.—Gye also maintains that chicken sarcoma is not peculiar, as hitherto believed, and that a particular mouse sarcoma will sometimes yield an infective filtrate. In this case, however, a special technique had to be employed, the original method of Rous proving unsuccessful. This is a discovery of much significance and it seems possible that an extrinsic origin may be found in the case of other cancers in the near future.

The virus of Rous sarcoma has been presumed to be particulate as it is held back by the finer grades of filter, and recently Barnard, using ultra-violet light, has obtained photographs of small globoid bodies about 0.1μ in diameter from cultures of the virus. These small bodies occurred in masses, suggesting colonies. They were not discovered in the medium before inoculation or when the cultivation of the virus proved unsuccessful. Whether they represent the microbes or aggregations of colloidal particles produced from the proteins of the medium by chemical changes associated with the growth of the virus occurring therein, is not at present determined.

Plant Diseases.—Filterable organisms are also responsible for many diseases of plants (*see* PLANT PATHOLOGY). In fact, their existence was first brought to light by Iwanowski in 1892 in connection with the mosaic disease of the tobacco plant. Iwanowski's discovery was lost sight of and the fact was rediscovered by Beijerinck in 1898. Many varieties of plants, including the potato, tomato, bean, peach, clover, pea, cucumber, turnip, spinach, *datura*, *hyoscyamus*, *capsicum*, sugar-cane, maize, sorghum and various grasses suffer from mosaic diseases. In most mosaic diseases the only obvious lesion is bleaching of the leaves in patches of varying extent, but sometimes, as in "leaf roll" of potatoes, "curly top" of beet and "spike" disease of sandalwood trees, definite destruction of tissue leading to malformation occurs. The loss of chlorophyll interferes with the nutrition of the plant by limiting the leaf area capable of utilizing the radiant energy of the sun for the building up of carbohydrate from carbonic acid and water. To this handicap local necrosis of portions of the leaf and stalk is in some varieties superadded. The economic effect of these diseases may be, as in the case of the mosaic of sugar-cane, almost negligible or, as in the case of "peach yellows" and the "spike" of sandalwood, serious, as it destroys these trees.

Between these extreme instances, the infection results in more or less diminution of crop. Only the growing leaves are affected. Nevertheless the virus extends throughout the plant and sometimes to the seeds. Mosaic diseases are very infectious. Mere handling of a healthy plant after touching an infected one is, in some instances, sufficient to transmit infection. The disease is spread by leaf flies or beetles and by grafting (*see* ENTOMOLOGY, ECONOMIC). The virus is not capable of maintaining itself in the soil. There is a large number of different viruses which produce mosaic diseases. Some of them infect more than one species of plant. They can also inhabit resistant species of plants without these manifesting any symptoms, but the disease can be transferred from resistant plants to susceptible species by insects or grafting. Many attempts have been made to propagate these

plant viruses in the laboratory upon plant-juices without success, but the virus of one of the mosaic diseases of the potato appears to have been recently cultivated by Olitzky.

Properties of Micro-organisms.—Little is known about most of these filterable viruses. They appear to be of various natures, and the only property common to them is minuteness. The parasite responsible for yellow fever is a small spirochaete, those occasioning bovine pleuro-pneumonia and human poliomyelitis are globoid in shape and just on the margin of visibility with the best microscopes.

It is not improbable that many of them flourish only inside the cells of animals and plants, which may explain the difficulty in cultivating them in artificial media. In some cases, small bodies of definite size, shape and staining characteristics are always to be seen in the cells at the seat of the lesion (trachoma, *molluscum contagiosum*, variola, vaccinia, bird-pox, typhus and Rocky Mountain spotted fevers). Whether these represent the microbe or granules in the cell contents produced under the influence of the virus is a matter of opinion. Until cultivation outside the body is achieved this controversy will not be settled.

Definite Results.—At present only the viruses of pleuro-pneumonia, poliomyelitis, yellow fever, chicken sarcoma and the microbe probably responsible for influenza have been certainly cultivated, although many claims to have accomplished this with other viruses have been made. Some of these viruses occur in the blood of the patient during the acute stage of the illness and are transported to a fresh host by the bite of blood-sucking insects.

Transmission of Infection.—The infections of yellow fever (*q.v.*) and dengue are conveyed by the mosquito (*Stegomyia fuscata*). That of papataci fever is transmitted by the sandfly (*Phlebotomus papatasi*) (see SANDELY FEVER) and that of typhus and trench fevers by lice (see INFECTIOUS FEVERS). With these three fevers, and also in the case of some of the mosaic diseases of plants which are transferred by leaf flies, some days elapse before the insect is capable of handing on the infection, indicating that an interval for the multiplication of the parasite is necessary. It is possible that a stage in the life-history of the parasite can only occur in the body of the insect host. Some filterable viruses, such as smallpox, cow-pox, foot-and-mouth disease and *molluscum contagiosum*, give rise to superficial lesions, and are spread by contact; others occasion catarrh of the respiratory passages and are distributed by coughing and intimate contact, as in distemper, measles and pleuro-pneumonia.

Conclusion.—Most filter-passing microbes which have been discovered hitherto cause disease of plants or animals. It would be strange if only parasitic forms existed, for the majority of the larger microbes are not pathogenic but are concerned with the multifarious putrefactive and fermentative changes in organic matter on the surface of the earth. Accordingly, it would be natural to suppose that sub-microscopic germs with similar activities would be ubiquitous. The indications, at present, are, however, against this supposition, and sub-microscopic dimensions seem to be an attribute, more especially, of germs which are parasitic upon animals and plants.

(C. J. M.)

FILTERS, LIGHT. Light filters are used to modify the light which traverses them by absorbing some portion of it either partially or completely. They may be used as liquid filters in the form of solutions or as solid filters, which may consist of coloured glasses or of films containing dyes. In some special cases, gases have been used as filters. Liquid filters are made by using solutions of salts or dyes held in glass troughs with parallel sides, while coloured glasses or stained films of gelatine or colloid are employed in a great variety of forms. On a small scale, gelatine light filters are generally made by coating glass with dyed gelatine and then cementing a cover glass with Canada balsam on to the dried gelatine film. On the large scale, however, they are prepared by coating the gelatine containing the necessary dyes upon plate glass and after drying, stripping the gelatine film off the glass, the filter being then used either as a gelatine film or cemented between optical glasses.

The colour of a filter is conditioned by its selective spectral absorption. Thus, a red filter absorbs the blue and green regions

of the spectrum; a blue filter, the red; a yellow filter, the blue; and a green filter, both the red and blue regions (see COLOUR). This selective absorption is best expressed by means of the absorption curve of the filter, which can be measured by an instrument combining the properties of a spectroscope and a photometer and known as a *spectrophotometer*.

Light filters may be classified as: (1) Selective filters, which transmit only a selected region of the spectrum, more or less narrow; (2) compensating filters, which have a more gradual absorption and which transmit in greater or less intensity most of the spectrum; and (3) subtractive filters, which absorb only a small portion of the spectrum and transmit the remainder, so that for every selective filter we can have theoretically a corresponding subtractive filter.

Application of Light Filters.—Filters used in photography may be classified according to their use as:

1. Orthochromatic filters, used to correct the selective sensitiveness of photographic materials in order give a reproduction of the brightness of coloured objects more closely approximating that perceived by the eye (see fig. 1). These are yellow in colour and are often known as *colour screens*. They are widely employed in practical photography.

2. Contrast filters, used to modify the brightness of some special colour or group of colours.

3. Selective filters, for two or three-colour photography with their corresponding synthetic projection filters if the processes of colour photography used are of the additive type (see fig. 2).

4. Compensating filters, used to adjust the light entering a photographic system in order to fulfill some particular condition required in colour photography.

For photomicrography, filters are used in the photography of stained sections and other objects displaying strong colours. Thus, if any colour is to be rendered as dark as possible, it must be viewed or photographed by light which is absorbed by the colour. On the other hand, in order

to render detail, it must be examined by the light which it transmits, so that insect preparations, for instance, which are strongly yellow, are best photographed by yellow or red light. Light filters are also employed for visual use with a microscope, blue and green filters being particularly valuable.

FILTRATION. In many industrial processes it is necessary to separate finely divided solid materials from liquids. The process of filtration consists in passing the liquid through a porous medium, which retains the solid particles. In some cases the recovery of the solid material is the main object; in others the filtration is done for the sake of purifying the liquid. Many types of filter are in use, differing in respect to (1) the various porous materials which are available for filtration, and (2) the construction of the apparatus in which these are applied.

Filter Materials.—The following are the main types of material which are in use:

1. Sheets of woven or felted material. These comprise porous filter paper, cotton, woollen or linen cloth, felt and woven metal.
2. Unwoven fibrous material, such as cotton wool, linen fibre, cellulose pulp, metal fibres, sponge.
3. Granular or powdered materials, such as gravel, sand, earth, coke, sawdust, cork.
4. Porous plates of stone, porcelain, carbon, silica, etc.

The choice of material depends upon (a) the fineness of the substances to be filtered, (b) the chemical nature of the liquid, (c) convenience in collecting the solid material after filtration.

Laboratory Filtration.—Porous paper is generally used as the filter medium, being resistant to most of the liquids which require filtration. The commonest method of filtration is to fold a circular filter paper twice at right angles, and open it out to a cone with

FIG. 1.—ABSORPTION SPECTRUM OF K-2 ORTHOCHROMATIC FILTER

FIG. 2.—ABSORPTION SPECTRA OF THREE COLOUR FILTERS

three thicknesses of paper at one side and one at the other. This is placed in a conical glass funnel, and the liquid is poured into it. In some cases, the filter funnel is provided with a hot-water jacket to keep the liquid warm during filtration. Filter paper is also manufactured in the form of thimbles, for extractions with solvents, such as alcohol and ether, in special apparatus. The Buchner funnel is made of porcelain and has a flat, perforated bottom on which a circular filter paper is placed. This form of filter has the advantage that the filtration may be assisted by the application of suction below the filter. The Gooch crucible is a porcelain cup with a perforated bottom. A thin layer of asbestos serves as the filter, and the crucible can be weighed, after drying, to ascertain the weight of solid material collected. Filters are now made for laboratory use in which the porous material consists of a fritted mass of hard glass, which has been ground and sieved to a definite degree of fineness. This is made into discs, which are fused into various types of glass apparatus, and are resistant to almost all chemical reagents.

Filtration of Drinking Water.—Domestic filters are usually supplied in the form of earthenware vessels with filter beds of charcoal; in some cases filters of paper, asbestos or stone are used. It was originally thought that charcoal filters would unfaillingly remove micro-organisms, but the action was subsequently found to be less complete than had been believed. Indeed, if the filter material be not removed at intervals, it may become the seat of organic growths. Large-scale filtration of town supplies of water is generally effected in sand filters.

Industrial Filtration.—When possible, it is advantageous to allow the solid precipitate to settle in the liquor for some time, and to run off as much as possible of the clear liquid. The sediment may then be stirred up with water, allowed to settle, and the liquid again decanted, so as to minimise the bulk of liquor to be filtered, and to facilitate the subsequent washing. The design of industrial filters varies according to the requirements. The chief considerations are that the filter shall present a maximum available surface without occupying too much factory space, that it shall withstand the required pressures, that it shall not be easily clogged, but shall be readily cleaned and easily controlled at all points. In some cases filters are designed to work continuously. Simplicity and economy of construction often outweigh all other considerations; thus for many purposes it is sufficient to filter through a bed of sand, or through a simple sheet of cloth resting on a flat, perforated support. Suspended bags of cloth are also frequently used, and have the advantage that the bag can be squeezed or wrung out after filtration to remove as much liquor as possible from the solid material.

Vacuum and Pressure Filters.—As in laboratory filtration, suction is frequently applied to accelerate the flow of liquid. A filter cloth is spread on a perforated plate of earthenware or other material, and the receiver into which the filtrate flows is connected with a vacuum pump. Conversely, pressure may be applied to the surface of the liquid in the filter. In place of cloth filters, porous plates are sometimes used; these may be either flat plates or cylindrical "candles" of porous material, presenting an increased filter area. Leaf filters may be used either for suction or pressure. A typical form of leaf consists of a rectangular frame of perforated pipes to which is attached a stiff, corrugated coating of coconut matting or other material, and the whole enveloped by a cloth bag. The liquid passes from the exterior to the interior of the leaf, and is assisted either by external pressure or by internal suction. A filtering unit consists of a number of parallel leaves, thus presenting a large filtering surface.

Filter presses are somewhat similar in principle. In one form, recessed plates are supported on a framework, so that they can be firmly pressed together by a screw press. Sheets of cloth are placed between the plates, and thus, when the filter press is assembled, it forms a series of narrow partitions separated by cloth filters. Channels are provided so that the sludge to be filtered can be forced under pressure between the cloth sheets, and the filtered liquid is collected from taps at the bottom of the plates. After filtration and washing, if necessary, the plates are separated, and the cake of solid material is removed. In place of recessed plates,

some filter presses have alternate plates and distance frames.

In centrifuges the filtration is assisted by the rapid rotation of a circular pan. The periphery of the pan is perforated, and covered on its inner side with a filter cloth, supported by a basket of metal. The rapid rotation (up to about 1,000 revs. per min.) whizzes the liquid through the filter, with a force several hundred times greater than in gravity filtration.

Continuous Filters.—In the above-mentioned filters, the solid material has to be collected at intervals, and this necessitates interrupting the filtering operation. Continuous filtration can be effected by rotary filters. A hollow drum is supported in such a way that it can be rotated on a horizontal axis. The periphery of the drum is perforated and is covered with a filter cloth, and the drum dips into the liquid to be filtered. By suction, the liquid is drawn through the filter cloth to the interior of the drum, and the solid remains on the outside. The drum rotates slowly, and a scraper is fixed in such a position that it scrapes off the solid material continuously. In some cases, rotating discs are similarly used. A recent advance in filtration methods is the stream-line filter, which permits of the separation of extremely finely divided solid matter, which would pass through ordinary filter cloths. The liquid is forced through the edge of a pack of sheets of paper pressed tightly together. The channels between the sheets are so minute that the finest precipitates are retained. The filter is made in various forms to permit of continuous filtration, etc.

Coagulation as an aid to Filtration.—The greatest difficulties in filtration are presented by slimy substances, which clog the filter. Application of increased pressure only accentuates the difficulty, and considerable importance attaches to methods whereby the slimy material may be caused to clot together and settle out. This can be effected by the addition of kieselguhr, fuller's earth, clay, talc, silica-gel and various carbonates. Another procedure is to coat the filter with a layer of finely divided kieselguhr, boneblack, sawdust or other finely porous material, which retains the slime and prevents it from penetrating into the filter material.

(R. C. F.)

FIMBRIA, GAIUS FLAVIUS (d. 84 B.C.), Roman soldier, partisan of Marius. He was sent to Asia in 86 B.C. as legate to L. Valerius Flaccus, but quarrelled with him and was dismissed. Taking advantage of the absence of Flaccus at Chalcedon Frimbia revolted and slew Flaccus at Nicomedia. He then took command of the army and obtained several successes against Mithridates, whom he shut up in Pitane on the coast of Aeolis, and would undoubtedly have captured him had Lucullus co-operated with the fleet. Fimbria treated most cruelly all people of Asia who had revolted against Rome or sided with Sulla. Having gained admission to Ilium by declaring that, as a Roman, he was friendly, he massacred the inhabitants and burnt the place to the ground. But in 84 Sulla crossed over from Greece to Asia, made peace with Mithridates, and turned his arms against Fimbria, who committed suicide. His troops were made to serve in Asia till the end of the third Mithridatic War.

See *ROME: History*; and *SULLA* and *MARTUS*.

FIMBRIATE, a zoological and botanical term meaning fringed (Lat. *fimbriae*, fringe). In heraldry (*q.v.*) a bearing with a narrow edge or border is "fimbriate" or "fimbriated."

FINALE, a term in music for the concluding movement in an instrumental composition, whether symphony, concerto, or sonata, and in opera of the older type the concluding section of each act. Among instrumental examples the great choral finale to Beethoven's 9th symphony, and, among operatic finales, that of Mozart's *Nozze di Figaro*, to the second act, are famous.

FINANCE is that part of practical affairs which is concerned with money taken in a broad sense, to include not only that which is legally money (such as coin and paper money) but also bank credit or "credit money." Without suggesting that a word of such extensive practical application can be adequately defined by any simple formula, we may indicate its significance by saying that finance is "the art of providing the means of payment." The immediate aim thereby assigned to finance in any business is simply that of maintaining at all times an adequate cash balance (in money or bank credit). But the means employed include all

the multifarious methods of borrowing money and of exchanging one sort of pecuniary right against another.

Subdivisions of Finance.—The following are the principal categories of finance in commercial enterprise:

(1) *Banking.* Banks create credit money by lending, and supply their customers with the means of payment.

(2) *The Money Market.* Closely associated with the banks, but distinguishable from them, is the money market, an organization for dealing competitively with short-term lending in the form of bills of exchange or day-to-day loans.

(3) *The Investment Market, viz.:*

(a) *The Stock Exchange*, where stocks, shares, bonds and debentures are bought and sold,

(b) *New Capital Issues*, or the raising of funds from investors for the promotion of new capital enterprises.

(4) *The Foreign Exchange Market*, where the means of payment in one country are exchanged for the means of payment in another.

(5) *Insurance*, including life insurance, which is a form of investment, and insurance against risks (such as fire or shipwreck).

Public Finance.—This is in a class by itself. Governments raise the means of payment:

(a) by taxation,

(b) by borrowing.

Taxation means compulsory contributions of money taken by authority of law from members of the community.

Governments have other resources. On the one hand they obtain money from state-owned enterprises, such as posts, telegraphs, telephones, railways or from state-owned property, such as forests or mines. On the other hand they exact services in kind, such as compulsory military service. But in any highly developed community taxation is the principal resource.

If revenue fails to meet expenditure, the deficiency has to be made good by borrowing.

Financial policy has to decide (1) how much revenue is to be raised and by what taxes, (2) how much public expenditure there is to be, and in what directions it is to be limited, (3) whether any of the expenditure is to be met by borrowing, and, if so, how much, and on what terms the money is to be borrowed.

The generally accepted principle is that revenue ought to meet expenditure, except

(1) expenditure of a clearly capital character, such as public buildings or income-yielding plant;

(2) emergency expenditure, so large in amount that to cover it by taxation would be unduly burdensome or even entirely impracticable, e.g., war expenditure.

Control of Public Expenditure.—In order to secure a balance between revenue and expenditure outside these exceptional cases, some control over expenditure is needed.

This control takes several forms:

(1) *Parliamentary Control.* Parliaments are given the right of voting the public expenditure under a number of separate categories (sometimes elaborately and minutely classified), and the executive government is required to keep within the vote under every head.

(2) *Executive Control.* Every department is required to conform to the directions of the ministry of finance in regard to its expenditure. (A particularly drastic and searching control is exercised by the Treasury in Great Britain).

(3) *Accountability.* To be effective, all forms of control require some system which will bring to light any cases in which the directions given have been contravened. There must be a thorough system of audit devised for this purpose.

In limiting expenditure it is necessary to weigh in the balance the advantages of the expenditure which is in question, against the disadvantages of the taxation which would have to be imposed to meet it. The ministry of finance, in exercising control over the various heads of expenditure and in determining what taxes are to be imposed, retained or remitted, should constantly keep that comparison in view.

It is also the function of the ministry of finance to consider what items of expenditure may be met from borrowing, what

form the borrowing should take, what provision should be made for sinking fund to pay off debt, and what arrangements should be made for dealing with debt maturities and conversions. In all these matters, while it is for the ministry of finance to make proposals, the measures actually taken are usually regulated by statutory enactments.

A minister of finance also requires authority for temporary borrowing. Primarily temporary borrowing is needed to meet a temporary lag of revenue behind expenditure, or to meet emergency expenditure in the interval before a permanent loan can be issued. But there is a danger that it may extend beyond these limits. Temporary borrowing can be effected through banks, which create the credit money which they lend. An excessive floating debt is a great danger because it may lead on to inflation of the currency. Inflation may be regarded as a breakdown of public finance. The government, having failed to provide the means of payment by means of taxation and genuine borrowing, has resort to the creation of bank credit to fill the gap.

Governments and legislatures take responsibility for the provision of currency for the community. But sound principle generally requires this function to be kept as separate as possible from the finance of the public service. The administration of the currency is (or ought to be) directed to the provision of the means of payment for the community generally and not for the government in particular.

Public finance includes, besides the finances of governments, the finances of local authorities (municipalities, county councils, communes, etc.). Local authorities are usually given limited taxing powers by statute and their borrowing powers are also restricted and supervised. Sometimes they also receive subsidies from the government out of the national tax revenue.

(R. G. H.)

FINANCE, ARTICLES ON. The subject of finance is treated here in many different articles, to which the following notes, together with the references in the General Index, will be a guide.

As to banking, reference should be made to the articles *BANKING AND CREDIT*; *CENTRAL BANKS*; *BANK*; *BANKS, HISTORY OF*; *MONEY*; *CHEQUE*; *INFLATION AND DEFLATION*; *CURRENCY*; *INTERNATIONAL PAYMENTS*.

As to the money market, the relative articles are *MONEY MARKET*; *BILL BROKER*; *DISCOUNT AND DISCOUNT HOUSES*; *MERCHANT BANKERS*; *BANK RATE*; *BILL OF EXCHANGE*.

As to the investment market, there are articles on *STOCK EXCHANGE*; *STOCKBROKER*; *INVESTMENT*; *OPTIONS*; *DIVIDEND*; *CAPITAL, EXPORT OF*; *BUILDING SOCIETIES*; *FRIENDLY SOCIETIES*, etc.

As to the foreign exchange market, articles can be consulted on *EXCHANGE, FOREIGN*; *BALANCE OF TRADE*; *BILL OF EXCHANGE*; *ARBITRAGE*.

Upon insurance, a series of articles can be consulted covering every part of the subject; see *INSURANCE*; *NATIONAL INSURANCE*; *UNEMPLOYMENT INSURANCE*; *INSURANCE, MISCELLANEOUS*; *FRIENDLY SOCIETIES* and the related articles under *EXPECTATION OF LIFE*; *ANNUITY*; *SUPERANNUATION*; *PENSIONS*; *WAR PENSIONS*; *LIFE TABLES*; *GENERAL AVERAGE*.

Turning to public finance, the general control of public expenditure is described under *PARLIAMENT*; *BUDGET*; *EXCHEQUER*; *ESTIMATES*; *SUPPLY*.

Upon the important subject of taxation, articles will be found under *TAXATION*; *INLAND REVENUE, BOARD OF*; *INLAND REVENUE DUTIES*; *CUSTOMS*; *STAMP DUTIES*; *INCOME TAX*; *ESTATE DUTIES*; *LAND TAXES*. There are separate articles on *INCOME TAX (ECONOMIC ASPECT)* and *INCOME TAX (IN PRACTICE)*. The article *INHERITANCE* should be read in connection with the treatment of *ESTATE DUTIES*.

As to public borrowing and public debt, a series of articles will be found under *NATIONAL DEBT*; *INTER-ALLIED DEBTS*; *FLOATING DEBT*; *SINKING FUND*; *WAR FINANCE*; *REPARATIONS AND DAWES PLAN*; *DEBT CONVERSION*. It should also be observed that under the title of each country a section devoted to finance gives important details. *LOCAL TAXATION* is treated under that heading.

A special article is devoted to the important subject of NA-

TIONAL SAVINGS.

FINANCE ACT: *see* BUDGET.

FINCH, a name applied (but almost always in combination, as bullfinch, chaffinch, etc.) to birds of the family *Fringillidae*. Generally speaking finches are small birds with a hard bill, living mainly on seeds, and characteristic of the Palaearctic region, where most of the very numerous species live.

See also BULLFINCH; CANARY; CHAFFINCH; HAWFINCH; SPARROW; GREENFINCH; GROSBEAK; LINNET; CROSSBILL; SISKIN; GOLDFINCH; REDPOLL; BOBOLINK; BUNTING.

FINCH, FINCH-HATTON, English family. Sir Thomas Finch (d. 1563), who was knighted for his share in suppressing Sir T. Wyatt's insurrection against Queen Mary, was the son and heir of Sir William Finch, who was knighted in 1513. He was the father of Sir Moyle Finch (d. 1614), created a baronet in 1611, whose widow Elizabeth (daughter of Sir Thomas Heneage) was created a peeress as countess of Maidstone in 1623 and countess of Winchilsea in 1628; and also of Sir Henry Finch (1558-1625), whose son John, Baron Finch of Fordwich (1584-1660), is separately noticed. Thomas, eldest son of Sir Moyle, succeeded his mother as first earl of Winchilsea; and Sir Heneage, the fourth son (d. 1631), was the speaker of the House of Commons, whose son Heneage (1621-1682), Lord chancellor, was created earl of Nottingham in 1675. The latter's second son Heneage (1649-1719) was created earl of Aylesford in 1714. The earldoms of Winchilsea and Nottingham became united in 1729, when the fifth earl of Winchilsea died, leaving no son, and the title passed to his cousin the second earl of Nottingham, the earldom of Nottingham having since then been held by the earl of Winchilsea. In 1826, on the death of the ninth earl of Winchilsea and fifth of Nottingham, his cousin George William Finch-Hatton succeeded to the titles, the additional surname of Hatton (since held in this line) having been assumed in 1764 by his father under the will of an aunt, a daughter of Christopher, Viscount Hatton (1632-1706).

FINCH OF FORDWICH, JOHN FINCH, BARON (1584-1660), generally known as Sir John Finch, English judge, was born on Sept. 17, 1584, and was called to the bar in 1611. He became recorder of Canterbury in 1617. In 1626 he was appointed king's counsel and attorney-general to the queen, and was knighted. In 1628 he was elected speaker of the House of Commons. He was the speaker who was held down in his chair by Holles and others on the occasion of Sir John Eliot's resolution on tonnage and poundage. In 1634 he became chief justice of the court of common pleas, and zealously upheld the king's prerogative. As chief justice he displayed great brutality in the cases of William Prynne and John Langton. He presided over the trial of John Hampden for non-payment of ship-money. He became lord keeper in 1640 and was created Baron Finch of Fordwich. One of the first acts of the Long Parliament, which met in the same year, was his impeachment. He took refuge in Holland, and in 1660 was one of the commissioners for the trial of the regicides. He died Nov. 27, 1660.

FINCHLEY, an urban district in the Finchley parliamentary division of Middlesex, England, 7 m. N.W. of St. Paul's cathedral, London, with stations, Finchley and East Finchley on the L.N.E. railway. Pop. (1931) 58,961. The parish church of St. Mary (restored 1873) has some interesting ancient brasses. Finchley extends north from Hampstead and Highgate between Hornsey on the east and Hendon on the west, and consists of East Finchley or "East End," Finchley proper or Church End, and North Finchley or Woodside Park. Its pleasant, healthy situation has caused Finchley to become a populous residential district. Finchley Common was formerly one of the most notorious resorts of highwaymen near London; the Great North Road crossed it, and it was a haunt of Dick Turpin and Jack Sheppard; the latter was captured here in 1724. The Common has not been preserved from the builder. In 1660 George Monk, marching on London, made his camp on the Common, and in 1745 a regular and volunteer force encamped here, prepared to resist Prince Charles Edward, who was at Derby. The gathering of this force inspired Hogarth's famous picture, the "March of the Guards to Finchley." Christ's college school, with two other secondary schools, is controlled

by the county and district councils. There is a memorial hospital and a branch of the National Hospital for the Paralyzed and Epileptic. Finchley council has its own electricity undertaking and controls a considerable acreage of open space and playing fields, besides having an extensive town-planning scheme.

FINCK, FRIEDRICH AUGUST VON (1718-1766), Prussian soldier, was born at Strelitz on Nov. 25, 1718. He had been a soldier of fortune in Austria and in Russia until in 1742 he became aide-de-camp to Frederick the Great of Prussia. After the battle of Kolin (June 18, 1757) he was made colonel, and at the end of 1757 major-general. At the beginning of 1759 Finck became lieutenant-general. He commanded a corps at the disastrous battle of Kunersdorf, where he rallied the beaten Prussians. Later in the year he fought, with General Wunsch, the action of Korbitz (Sept. 21) in which the Austrians and the contingents of the minor states of the Empire were sharply defeated. But the catastrophe of Maxen (*see* SEVEN YEARS' WAR) put an end to his active career, though he acted strictly on Frederick's orders. Cut off by greatly superior numbers, he was forced to surrender with some 11,000 men (Nov. 21, 1759). He was court-martialled, cashiered and imprisoned in a fortress. At the expiry of this term Finck entered the Danish service as general of infantry. He died at Copenhagen on Feb. 22, 1766.

FINCK, HEINRICH (d. 1527), German musical composer, was probably born at Bamberg, but nothing is certainly known either of the place or date of his birth. Between 1492 and 1506 he was a musician in, and later possibly conductor of, the court orchestra of successive kings of Poland at Warsaw. He held the post of conductor at Stuttgart from 1510 till about 1519. His works, mostly part songs and other vocal compositions, show great musical knowledge, and amongst the early masters of the German school he holds a high position.

FINCK, HENRY THEOPHILUS (1854-1926), author and music critic, was born at Bethel, Mo., Sept. 22, 1854. At Harvard he won highest honours in philosophy, next becoming a resident graduate at Cambridge, 1877-78. He secured a Harris fellowship, and studied psychology in Berlin, Heidelberg, and Vienna, 1878-81, then intending to become a professor in the subject. It was a commission from the *New York World* to cover the Niebelungen performance, first Bayreuth festival, which changed his career. In 1881 he was appointed music critic of the *New York Evening Post*, holding the position 43 years, until 1924. He championed Wagner, Chopin, Liszt, Grieg, and MacDowell, but was proudest of his work to popularize Grieg. Of extraordinary versatility, he wrote on gardening, gastronomy (*Food and Flavour* being notable), travel, as well as voluminously on music, his books totalling 24. He died at Rumford Falls, Me., Oct. 1, 1926.

FINDEN, WILLIAM (1787-1852), English line engraver, was born in 1787. He served his apprenticeship to one James Mitton, but appears to have owed far more to the influence of James Heath. His first employment on his own account was engraving illustrations for books, and among the most noteworthy of these early plates were Smirke's illustrations to *Don Quixote*. His younger brother, Edward Finden, worked in conjunction with him, and as time went on and the number of their commissions increased, they employed several assistants, with a consequent deterioration in the later plates issued by them. The largest plate executed by William Finden was the portrait of King George IV. seated on a sofa, after the painting by Sir Thomas Lawrence. Finden's next and happiest works on a large scale were the "Highlander's Return" and the "Village Festival," after Wilkie. A series of landscape and portrait illustrations to the life and works of Byron executed by the Findens appeared in 1833 and following years. But by his *Gallery of British Art* (in 15 parts, 1838-40), the most costly and best of these ventures, he lost the fruits of all his former success. Finden's last undertaking was an engraving on a large scale of Hilton's "Crucifixion." He died in London on Sept. 20, 1852.

FINDLAY, SIR GEORGE (1829-1893), English railway manager, was born at Rainhill, Lancashire, on May 18, 1829. He was originally a stonemason, rose to be in charge of railway con-

struction operations on the Shrewsbury and Hereford line, and eventually (1880) to the position of general manager of the L.N.W. railway. He died at Edgware, Middlesex, on March 26, 1893.

FINDLAY, JOHN RITCHIE (1824-1898), Scottish newspaper owner and philanthropist, was born at Arbroath on Oct. 21, 1824, and was educated at Edinburgh university. He entered first the publishing office and then the editorial department of the *Scotsman*, became a partner in the paper in 1868, and in 1870 inherited the greater part of the property from John Ritchie, the founder. He presented to the nation the Scottish National Portrait Gallery, opened in Edinburgh in 1889, and he contributed largely to the collections of the Scottish National Gallery. He died at Aberdeen, Banffshire, on Oct. 16, 1898.

FINDLAY, a city of north-western Ohio, U.S.A., on the Blanchard river; the county seat of Hancock county. It is on Federal highway 25 and several State roads, and is served by the Baltimore and Ohio, the Big Four, the New York Central, and the Nickel Plate railways, and by three inter-urban electric lines. The population was 17,021 in 1920; 1930 it was 10,363. The city lies on gently rolling ground, 780 ft. above sea-level, surrounded by a rich agricultural and stock-raising region, in the heart of the Ohio oil and gas fields. It is the seat of Findlay college (Church of God), chartered in 1882. The many manufactures (valued in 1927 at \$15,387,162) include petroleum products, electric porcelain, ditching machines, rubber tires, railroad dump cars, beet sugar and cigars. During the War of 1812 a fort was built here by Col. James Findlay, commanding an advance regiment for General Hull. The town was laid out in 1821, incorporated as a village in 1838 and chartered as a city in 1890. Oil and gas were discovered in 1886, and the population rose to 18,553 in 1890.

FINE, in the legal sense, a pecuniary penalty inflicted for the less serious offences. Fines are necessarily discretionary as to amount; but a maximum is generally fixed when the penalty is imposed by statute, and it is an old constitutional maxim that fines must not be unreasonable. In Magna Carta, c. iii, it is ordained "*Liber homo non amercietur pro parvo delicto nisi secundum modum ipsius delicti, et pro magno delicto secundum magnitudinem delicti.*"

The term is also applied to payments formerly made to the lord of a manor on the alienation of land held according to the custom of the manor; to payments made by a lessee on a renewal of a lease, and to other similar payments. Fine also denotes a fictitious suit at law, which played the part of a conveyance of landed property. (See FICTIONS.) This, with the kindred fiction of recoveries, was abolished by the Fines and Recoveries Act, 1833, which substituted a deed enrolled in the court of chancery. (See also ENTAIL; EJECTMENT; PROCLAMATION.)

FINE ARTS. In a general sense the fine arts are those among the arts and industries which man cultivates for his necessities or conveniences, and which minister also to his *love of beauty*. Architecture, for example, providing shelter and accommodation, offers in its use and mechanic perfection visions of the strength, fitness, harmony and proportion of parts; but also by its dispositions and contrasts of light and shade; by colour and enrichments; and by variety and relation of contours, surfaces and intervals, has decorative competence and so is accounted a fine art. In the graphic arts we observe that love of beauty can cover the interest of visual excitement such as caricature and the grotesque. The terrible, the painful, the squalid, the degraded,—in a word every variety of the significant,—may be brought within the province of fine art on the ground that the art of man springs from his impulse to create, and thereby associates with creation the kindred pleasure, that of witnessing and appreciating what is made to attract that interest. In common usage there is often confusion between art-making and art-seeing as measures of art-values. But the word *fine* has a special significance for aesthetic creation, as conditioning its power over material.

"God saw creation that it was good," and "in the image of God," we read, "man was created." The word *image* admits the power of the artist to fine art vision and in this connection *design*

has a cognate association. On the other hand when the spectator of art finds pleasure or satisfaction in an executed work of craft, his mental exaltation comes in seeing what the creator imaged and recognizing its *fineness*. Such recognition may come in mutual co-ordination with the spirit of the age—acting as a mass instinct in the broad sense of the designer and his clients being of one mind. But it may go on to the schooling of temperament, and so become the conscious *taste*, acting as a gauge or rule upon the *images* of craft. Such alternating relations and the constant varieties in human *design* and *taste* have given rise to a formidable body of speculation and discussion. The present article, dealing with concrete processes and the material results of the creative activities of man, defines them as fine art in general; classifies the fine arts in their main distinctions and discusses their historical aspects in various phases of image-design and taste-association.

A popular and established theory distinguishes *art* from *nature*, in that man is deliberately the fabricator of art, while nature functions outside him. Design itself is a dexterity of which one of the essential qualities is the will and premeditation of the artist. We reckon the songs of birds as *instinctive*, and this "epithet colours the skylark's outpourings as of a different order from the poet's." The distinction is, however, modified as we realize that the power of *imaging* has grown by natural instinct in evolution out of the desire to make. The earliest workers in sculpture or painting were the cave-dwellers of the prehistoric ages who scratched the outlines of animals of the chase on implements or who made models of them upon their cave walls. Children can be seen still as innocent artists making for themselves, just for the pleasure of seeing what they make. So the original or rudimentary type of the architect-artists was evolved when a savage found his satisfaction in tidiness and developed an instinct of fitness in his ordering of the skins or the tree branches that covered his tent or hut. So the first artificer was a maker of club or spear to his pleasure in its handling—the primitive art-monger having small reason for pleasing anybody but himself.

As early in history the primitive dancer and singer were seeking their audiences, so the artificer wrought, with an eye to please others too. The historical sequences of art pass from *craft* to *style*; and it will be shown that as long as these were in full accord, the current association was working for an instinctive satisfaction and it has its *images* in the balanced economy of craft and taste; but when *taste* or some imported association of style began to lecture workmanship, art lost its creative will, and craft decayed.

There is accounted also a disinterested sphere for the art instinct in that the spectator has a share in the designer's ideal and a sympathetic, indirect satisfaction for himself therefrom. But the first-hand pleasure of design is that of the creative imagination; and in its spontaneous working we have engaged "incalculably complex groups of faculties, reminiscences, preferences, emotions," that constitute the *vision* of the artist. The product is a finished work of craft, and so has its power to please, graded by craft capacity. But skill in any useful art means a practised conduct of the hand, fashioning material to a particular end. The artist differs from the mechanical workman in the nature of his *images* of beauty arising in the material associations of his craft, and so he is consciously solving aesthetic problems according to the excitation of an ordering as well as a creating instinct in himself.

The conclusion is that images of beauty make the substance of the fine arts and create the several qualifications of architecture, sculpture and painting. Architecture, for example, is a *mistress art* in that its occasions demand the full substance of aesthetic vision. "The architect has liberty for the disposition of his masses, lines, colours, alternations of light and shadow, of plain and ornamented surface, and the rest." In him *material* association formulates his images, because in supplying definite accommodations, he has mechanical necessities to meet in laws of weight, thrust, support, resistance and other properties of solid matter. The sculptor and the painter, too, have their spheres of action in physical appearance. But the sculptor is creating surface aspects by a mechanical tooling. He materializes his *images* by cutting them into stone,

marble or wood, or by shaping them in metal, plaster, etc. The painter finds to his hand a more extended range of natural facts and appearances, because his pictorial images are flat on a plane surface, as worked in terms of his painting tools. In all three fine arts, however, the artist's operation has its every bloom and virtue, in the nature of a material regulation. The rank of artistry may be gauged by the spectator, but the working test has been the artist's power to grasp and realize his vision in the terms of his craft. It is claimed for the fine arts that their ideality of form and colour is a sort of "play—a free vent for an energy over and above what is needed to be spent upon the conservation, perpetuation or protection of life." However, the superfluous or optional character of art is that it comes in the instinctive gratification of a free creative choice and by such transmitted pleasure, public taste is gratified.

We are following in general terms R. G. Collingwood's *Outlines of the Philosophy of Art* in that he defines art (1) as the creation of objects, or the pursuit of activities called works of art by people called artists—works distinguished as products intended to be beautiful; (2) as the creation of objects or the pursuit of activities called artificial as opposed to natural—that is objects created or activities pursued by human beings consciously free to control their natural impulses and to organize their life on plan; (3) as creating that frame of mind which we call artistic, the frame of mind in which we are aware of beauty. While the mechanical pleasure of tool-using bridges the distinction between art and industry—so the spiritual sense of the *image* brings fine art into line with literature and music—which are not arts of objective completion, but of powers of interpretation.

The systematists of the 19th century thought themselves competent to grade the fine arts in terms of philosophical analysis. Hegel ranged architecture, sculpture and painting as coming in a natural order of evolution—ancient architecture the expression of obscure symbolic ideas; sculpture the classic passage into clear-cut, lucid thought; painting the modern sum of romantic ideality. Herbert Spencer seems to track out the passage from ancient to modern—as one from the hieratic simplicity of the architectural monument to the decorative complexity of the sculptural and pictorial uses of advanced city life, and finally in our civilization, the elaborate and emotional complex which moderns account as the art of the picture. Such analysis can be seen to rank the painter's genius as the ultimate crystallization. And in this sense art history is read nowadays as character analysis, and written up as a sublimation of temperament. Criticism was initiated when Vasari wrote the lives of the Renaissance painters in 1550, and to this day we have his successors, decorating the story of art with literary values. The temperamental factor in the development of painting has been well studied by D. S. MacColl, who distinguishes three outstanding varieties: "The Olympian painter," he says, "is king and master in a world made for his use; he is on the gods' side and his art mirrors their perfection of form, their happiness in majesty of calm possession. The Titan is rebel against the Powers, his spirit is of passion and strife"; and his art develops as a social revolution. A third temperament is of the mystic who "seeks in humility and meekness values outside things visible," and recognizing the nothingness of assertion, surrenders his perception of reality to an inner sense of second-sight. With increasing distinctness in the last 300 years the temperamental conditions of fine art have marbled the basal colouring of the picture habit in associations of schools and cliques. Olympians, Titans and mystics appear master individualities, linking up the Renaissance with our painting. Olympian graces appear in pictorial procession from Raphael's allegories to the flattered portraits of humanity and circumstance which have in the 16th, 17th and 18th centuries made the staple of fashionable master craft. In idyllic atmospheres have been stayed the contentments of the Dutch and French *genre*, its domestic atmosphere and homely landscape; and similarly the poetry and pleasantries of the English academicians has been steeped in a mild-mannered geniality. Titan mentality must be allowed to the painter scientist, such as Leonardo da Vinci; to Rembrandt adventuring into untrodden paths of chiaroscuro; to Salvator Rosa brigand hunting in the wild; to Breughel

sidling away to the fair-booth and *kermesse* dance. So too were the high-handed despisers of convention, Hogarth and Goya, handing on the torch to the rebellious anarchists of the French painting cliques. Yet there was the line of mystics too—Giorgione painting he knew not what; Velázquez finding a new wonder in the focus of the eye; El Greco imagining a chaos of line and colour; Blake making his mystery of ghostly hope and fear; Turner adventuring flights into the glory of the air; or Corot painting a fairy light for spring-time willows.

Temperament and circumstance have had to make literary standard values of fine art. Taine has laid stress on the vicissitudes of racial and political development for initiating or repressing pictorial genius. Fromentin, however, questions such deduction, observing how the Dutch innocence and simplicity were no reflection of the stirring life and dramatic heroism of the Netherlands revolt from Spain: whereas French painting in the 19th century was moulded continually to the trend of revolutionary politics. Latterly our experts are laying less stress on philosophical analysis and we may summarize the 20th century appraisal of art as, seeking practical definition, Sir C. J. Holmes in his *Notes on the Science of Picture-Making* gives the present-day conditions that govern picture practice.

"All great art, being emphatically personal, is accompanied by variation from previously existing standards of excellence. This personal variation is marked by a new intensity of feeling, by a new sense of vitality and by a new rhythm of pattern. All great artists are pioneers possessing these characteristics. In their followers, the second-rate artists, we find less intensity of feeling, less vitality and a feebler rhythmical sense. Emotion is the key-stone of painting as it is of poetry. What is not strongly felt is no material for the artist. The painter's emotion sums up and concentrates his experiences (imaginative or visual) in terms of rhythmical paint as the poet does in terms of rhythmical words. Theory is not a substitute for talent, but its necessary teacher. Principles of design are not rigid moulds into which the subject-matter of a work has to be squeezed. Their task is to suggest to the artist the particular means, by which each given subject can be perfectly expressed. Tradition is no more than the body of principles, which secure conformity between art and its contemporary environment. What is a perfect tradition for one period or climate may thus be a fatal influence in another period or climate, because it does not fit the changed conditions. Hence the danger of revivals of old methods. Systems of art teaching have commonly failed from not recognizing the necessity of progress, from enslavement to a fixed canon of ideal beauty. No such fixed canon of ideal beauty can be set up as a standard for future achievement. We cannot do again what has already been done by a great artist; we must do something different. Each field of artistic activity is exhausted by the first great artist who gathers a full harvest from it."

Art history in successions of style and in appraisal of art value has no verdict to offer as to what is *great art* in definition of greatness. We may say that fine artistry is figuration, yet also transfiguration; but to be proficient in his craft is the artist's necessity for himself; to be ideal is his instinct, for so he assures partnership with the spectator. Art history has been a serial evolution of art instincts crystallizing into styles. Their succession in world history may be indexed as ancient, classic, mediaeval and modern, but this is just to link up art manifestations with phases of human progress.

PROGRESSIVE ASPECT OF ARTS AND CRAFTS

The Magic or Attributive.—The primitive instincts of fine art can be taken as promotions of physical advantage, in handling a weapon, say, or as required for the successful covering of a hut. Then secondly, as adding to these instinctive joys the design-value of *taste*. The imitative representation of deer and mammoth upon weapons, the modelling and painting of animals in cave interiors were purposed "power" in magic sense:—the aesthetic capacity was insurance to the "devotee" of success in the chase—or such a control over the quarry as would, by creating its image to the hunter's mind, bring it to his hand. The visioned

reality was started in the sense of a religious exercise, as setting up profitable commerce with the unseen. Prehistoric art in Europe had millenniums of evolution, and in the height of its accomplishment toned form and colour into "images," that sophisticated art calls primary elements of design. Then in later cave paintings graphic sense loses touch with reality, passes into symbol and pattern, and so originates the alphabet—mind usurping the domain of craft.

The Hieratic and Palatial.—Political and religious intention evolved art aspects for both palaces and temples in many eras of earliest Asian arts. The cycles of Sumerian, Chaldean and Babylonian dominion illustrate the successions of conquering civilizations in the delta of the great rivers; on the back lands came the sinister aspects of Assyrian dominion; in central Asia Minor the Hittite; and later at Persepolis the Persian art. In the Nile basin were mounting to artistic fruition and dying away five dynastic periods of Egyptian style—succeeding one another in eras of 800 years or so. Priest and Pharaoh in long tradition controlled architecture, painting and sculpture, up to and even past the Hellenistic development of Greek style. The linking up of Egyptian craft design with magic is illustrated in the tomb-tablet of the Egyptian Mertissen where we read—c. 2200 B.C. "I was an artificer skilled in my art. I knew my art, how to represent the forms of going forth and returning—so that each limb was in its proper place. I knew how the figure of a man should go—the poising of the arm to bring the hippopotamus low—the carriage of a woman. I knew to make amulets against fire burning or floods drowning. No man could do this but I and the son of my body. Him has the God decreed to excel in art and I have seen his perfection in every sort of precious stone—in gold, in silver, in ivory and in ebony."

However, in the discovery of the Akhenatan cult and the Tutankhamen tomb there is record of a curious but short-lived break away from the craft formality of the Egyptian tradition. There came a generation of freer mentality and naturalistic observation before hieratic sway returned. The Egyptian connection has not been made clear with what excavation has revealed in Crete and other parts of the eastern Mediterranean basin. But a highly developed architecture of city building and palace decoration has been unearthed, showing *fresco* of high accomplishment, and works of relief modelling, that are of ordered and well-schooled taste. The successive periods are dated beside the later Egyptian eras, and in domestic and graphic expressions there were anticipated the furnishing and decorative crafts of the Italian Renaissance. The pottery, especially, was remarkable for a free rendering of flowers; the modelled animals in metal are distinct from the hieratic conventions of Egypt and Assyria. But to its art era came the dissipation of craft interest following on the commercial distribution of art products. There came, too, a razing of the Minoan palace-cities that had been the centres of this Mediterranean culture, and it passed away with small contribution to the genius of the "classic" style that was to register the next cycle of civilization.

The Classic Aspect.—Ancient art in Babylonia and Egypt was of local cult; its eras rose and fell with the dynastic empires and religions of the Near East. A wider area than the Mediterranean basin was due to the European era of style that came in the Greek and Roman developments of Hellenic civilization. A local nucleus of Dorian immigration and culture had descended from mid-Europe into a Mediterranean expansion in the 6th and 5th centuries B.C., strong enough to displace kindred evolutions, Ionian, Phoenician and Etruscan. After the Hellenic prime at Athens, there followed in Alexander's conquests the wide Hellenistic diffusion in displacement of Oriental survivals. Then in the 1st century B.C. the Roman empire-making founded a world-art, under the tutorship of Alexandrian craft, but under the aegis of Greek literature also. For 500 years the classic educations of society were controlling craft, and in them the classic arts flourished, declined and fell with the decay of the Roman empire of the west. In descent from it a decorative, aniconic graft of Greek craftsmanship remained to bear fruit in the Christian empire of Byzantium; so that in due course arch and

dome with concrete surfacing of structure were propagated in the Arab overflow of the Moslem faith. But neither Byzantine, nor Moslem art could secrete the *ethos* of Greek construction, nor the *images* of Greek humanism. The sculptural and pictorial arts of west Europe may claim to be Byzantinesque, but never, till the modern revivals, could architecture as a fine art think itself Greekesque.

The evolution, dispersion and decline of the Hellenic cult are a well-documented instance of a cycle with dominance for some centuries of culture. The essential national creation had been that of settlers in Greece, Dorian and Ionian stocks whose issue was expressed in the marble temple that had a human beauty enshrined in the material of its exercise. In humanity and simplicity Hellenic culture had an outlook on life that freed religion from the monster-godships which Minoan, Assyrian and Egyptian art had imaged. Greek sense dethroned the witch-doctor, and in the national piety of a citizen priesthood achieved its marble Parthenon. Hellenic sculpture was humanity in being, with the athlete as its model of manhood, and the maid as that of womanhood. The painting crafts resolved line and tone into an intellectual analysis of light, which in the Greek vase was shaped and figured as a ritual music. But the architect as chief craftsman, and the sculptor as priest of art came to be exploited abroad in literary translation of Hellenistic phrasing. Commercial associations of artists were engaged to found new cities and to set up Hellenistic types and standards of human beauty. In the grouping and arrangement of decorative themes the craftsman became a man of artistic choice: his dexterities were specialties in the sophisms of academic direction. The sculptor set portraiture of emotion and dress by the side of traditional representations of the gods and heroes. So the curve of Greek art passed on from Hellenic simplicity into Hellenistic elaboration and obtained the patronage of Roman culture; illustrating how craft associations first image style and then find their energy sapped by the extraneous association of learning. Hellenic art made its temple the crown and centre of a city's devotion; but the city of Athens lost its art when the idealisms of the Greek worship obtained cultured and political currency. Men and women had been deified in Greek sculpture—in Roman the imperial power was immortal, and for an emperor's divinity art formalized an imperial priesthood of fine art from Britain to Mesopotamia. Greece had been content with a simple constructive system of columns and horizontal entablatures; and in marble unity had invented and perfected her three successive modes, or orders of architecture—Doric, Ionic and Corinthian (*qq.v.*). But the genius of Rome found her imperial destiny in the dome and the triumphal arch. Her conglomerate creed covered Europe even as the Pantheon ceiled the lounge of her public bath. Her cosmos was graded as her amphitheatres were graded for her public shows. Indeed the triumphal arch, not the pediment, was symbol of her sovereignty: a vast constructiveness—temple, palace, bath, amphitheatre, forum and aqueduct, ordered and levelled her proletarian empire to be uniform in its imperial arts as in its legionary garrison. In the Roman house memorial sculpture was its ancestral cult, and filled the atrium with portrait statues and busts, and dilettante scholarship had a corresponding piety to the past in copies or studies of the ancient masterpieces in wall paintings of classic subject and perspective fancy. In the crafts of ancient Rome was consummated a decorating capacity that passed on to Byzantium, in turn bequeathing its *répôts* to mediaeval church-building.

Mediaeval Aspects.—The break up of west European civilization was completed in the barbarian over-runnings. For one year (A.D. 410) the great Rome is said to have been without a single inhabitant. Free painting and free sculpture ceased to exist and Italy lost or discontinued the crafts of building. For 500 years Christian churches took derelict columns and architraves from Pagan pillar avenues, using for their halls of religious service, arcades and apses from the market places of deserted cities. It was for the Byzantinesque Christians to use the big square bays of the Roman bath, and with dome construction to attach to its rubble surfaces mosaic pictures. But the free statue, in the religious cult of the East had come under inter-

dict, and for 600 years the sculptural arts were degraded to rudimentary and subordinate uses, to a graphic pettiness of ivory-carving and metal-chasing. Painting assumed a rigid hieratic imagery for the mosaic pictures of apses and vaults of churches, or was practiced in manuscripts and service-books according to the recipes of a cloistered monkish craft. The Carolingian clergy of Gaul and Germany had service-books and ivories as school text-books; but specially in earliest advance were the English crafts of sculpture and painting, appearing foremost in recovery of a religious freedom.

In Celtic-Nordic genius there matured the new aspects of fine art, but for them Romanesque and Gothic had as trainers and instructors the monastic institutions, which in or about the year 1000 under the patronage of the papal hierarchy were dominating European culture. Under the Cluniac expansion of abbey-building was propagated a gospel of craft practice for all the arts and sciences of life. As Dorian stock and Ionian schooling established the marble accomplishment of Greece, so the fine art of stone found in the mixture of race and church culture the cradle of an era. Stone was the preciousness wrought, masoned, sculptured and lifted to the sky. The built church was the service-book of Christian civilization in which all the philosophy of four centuries wrote itself as art. In Cluniac sculpture the figure grew out of the stone, and the statue out of the pillar; in the Cistercian abbey fine art was the mason's refinement of structural economy; in the secular and episcopal schooling of religious pomp and circumstance came the towering majesty of the Gothic cathedral. In the 13th century the mason had taken fine art to the summit of craft execution. But in France before the end of it the vitality of cathedral structure was ceasing to animate masonry and the tool of the carver became specious for the accomplishment of the ivory image or the enamelled casket. The master-masonry of French architecture traversed Europe, but as inventive of style there had succeeded the decorated creation of the English 14th century to which associations of chivalry lent an aesthetic life. This was especially distinguished in memorial tombs, and in the sculpture of recumbent effigies worked by the English masons. In mid-14th century came the Black Death pestilences contributing such a set-back to the association of art and chivalry. There succeeded commerces of art furniture, and shop-use dictating the architectural enrichments of sculpture and painting. For two centuries Burgundian sculpture and Flemish painting acted as sponsors to a northern Renaissance, in which French Flamboyant with its veneers of decorative tracing made a last stand for continuance of Gothic style in architecture.

The phases of fine art practice ran their course with little distinctions of individuality in the artist. One mason or another made good in the quality of his work in association with the spirit of his time. Sculpture as *imaging* thought was still work of a *coementarius* or builder. After 1300 his capacity as king's mason, or goldsmith or as painter might take him into special appointment. But it was c. 1400 that the Sluters were sculptors, and the Van Eycks painters under the patronage of the dukes of Burgundy in formulating a new accomplishment for personal artistry. In Italy Pisani, Siennese and Florentines, painters and sculptors, emerging from the body of church furnishers, claimed fine art consciousness among their fellow craftsmen, and established cities as centres of special craft. For Italy had never taken Gothic style to its heart as the economic realization of stone construction, with enthusiasm for covering the greatest area and lifting the highest vault. By 1400 there had come to Italian art another quest, that of regathering the threads of the Byzantine arts of form and colour, to reweave the tapestry of classic scholarship.

Following the migration westward of Greek scholars, the classic forms of architecture became the study of Roman architects such as Brunelleschi and Alberti. But a more subtle sense of renewal attended the achievements of sculpture and painting, as Donatello and Masaccio took study of nature as a joy of life. For this renaissance was the ascetic ideal giving place to the physical. In power, beauty and grace the personages of the Christian faith and story were put into visible kindred with the heroes of ancient

paganism. Not as pedantry merely, but in the experiment of craft was fine art the heir of both antiquity and Christianity. The 15th century set Florence in the high place of art, in that she had become mistress of a culture at once scientific and religious, that had fine art and fine industry in united fellowship and competence to express the stirring life of republics, prince despots and church potentates, military captains and merchant princes vying with one another as patrons of the artist. There came a wealth of occasions for sculpturing and picturing, for monuments of civic and personal commemoration, for representations of pageantry and battle, for the allegoric conception of sacred and profane story. The Italian accomplishment of the *cinquecento* practised the heroic painting of fresco for the walls of council halls, for princes' palaces and popes' churches; classic loggias were furnished with marble and bronze statues; churches had pillared screens and monuments; while every city square showed its shrine or fountain; and every chapel its painted altar-piece. We may speak of this as a rebirth of artistic crafts but it was also the discovery of the *artist* as a man. A well patronized painter of illuminations, visiting Rome in 1536, has recorded himself as meeting Michelangelo and saying, "You Italians give the greatest honour, the greatest nobility and power to be more, to a man who is a splendid painter and sculptor, not as other nations do to generals and statesmen. With you as compared with great princes it is a painter alone that is called divine."

In this golden age came the use by painters of oil prepared as a drying pigment. With brighter and more facile brush technique than tempera-decorations, or the plasterer's art of wet fresco, studio or work-shop pictures became portable chattels in detachment from architectural structure. Thus were lost the intimate religious connections of fine art with altar use, as well as its broad treatments on chapel wall-surfaces. The brush attuned to new capacities of illustration and sensation, equipped the picture artist in Italy and northern Europe alike, for fresh fields of adventure, in which moral and aesthetic sensations had place. In a new capacity Italian purveyors of accomplished design were brought into the service of German emperors and French and English kings. The new art arrived for Europe in a succession of schools as Italian, Flemish, Dutch, Spanish, French and English "national" interpretations of a faculty that enriched the special fineness of the painter's art. But when Leonardo da Vinci as the honoured artist passed into the service of the dukes of Milan, when Raphael at Rome was the accepted decorator of the papal court, the artist-painter was no longer of one city, or of one ideal. Venetian colour had its commission as well as Florentine science and Titian was educated for a world-wide currency, as had been Michelangelo. They had become the representative European artists when subject-painting discovered that technical facility could replace religious idealization. With Raphael, Titian and Coreggio, art made terms with classic allegory, and, in the discovery of the palette sense, Titian and Rubens founded the dynasties of temperamental artistry. They were painters, courtiers and diplomats, as purveyors of authorized masterpieces. Rubens with his pupils and assistants, Van Dyck, Snyders, Teniers, etc., at work on courtly portraiture, on fleshly allegory, on boars and tigers, on tavern scenes, landscapes and village fêtes was in all just the Renaissance expert, commissioned to furnish art pieces for princely and private galleries and alike for church, palace or civic hall. His great work was a canvas fitted into the allotted space in wall surface; an exhibition entity in honour of the great art of painting.

Portraiture beyond the Alps, however, long kept to its mediaeval economics, and serious workmanship. Painters and engravers such as Dürer and Holbein were vowed to associations of design in craft essentially Gothic. The trades of the furniture arts in Brussels, Bruges or Antwerp, were scarcely touched by scholarship. But by 1600 the painter had been to Rome and Venice for his authorized education, and Rubens in the fire of his prodigious temperament, with true fusion of Flemish and Venetian qualities, in closing the Renaissance period was handing on an *art nouveau*. His Olympian creed, *Catholic* in its association with the Roman Church, and *Classic* in the doctrines of Roman virtuosity ruled

taste for half the world. The gilded luxury of it became an accepted tradition for all the craft interests of civilization and, for some two hundred years, the fine arts in all European countries were accepting the Italian pedantries of design. The Palladian orders, popularized as patterns, or examples of ancient scholarship, and their materializing in stone, were propaganda for that new vision of art which established correctness to pattern that became the stock in trade of accomplished architectures in France and the Low Countries, in mid Europe and Spain, and at last in England, each country conforming its style to its assimilation of book knowledge, but still by means of material needs, instincts and traditions, capable of giving to classic uniformity a national economy of style.

The 17th, 18th and 19th Centuries.—In Italy the outstanding figure of the 17th century was that of the architect and sculptor Bernini. In works of fountain and monument he visioned a new sensibility for masonry, that has acquired the name of Baroque. The Palladian conventions were endowed with a specious virtuosity of curved and flowing rhythm that remained in the Latin countries for long the accepted trade-mark of classic decoration. Its free modelling and clear colour scale was specially the birthright of Jesuit Rococo, which, born of the counter Reformation was carried round the world in the Catholic churches of the Spanish and Portuguese Indies. In Baroque and Rococo was the era of fine workmanship that for two centuries adorned Italian, Flemish and French styles. Art-workers grouped for the production of what is useful and fine in its degree—who deserved the place and name that the ancient Greek gave them in the word *Tékτων* (artificers)—initiated a style of salon decoration and furniture, for which Louis XIV.'s minister Colbert organized a system of State factories and academies of art. The architectural stylist had at his beck figure sculptors, picture painters, potters, weavers, smiths, gold workers, glass and china makers. In forms of rococo artificiality every natural form was translated with no restraint of either structural or religious conscience. The variety and exuberance of craft device, with its perfect finish, made the Louis periods text-books for decorative magnificence in Europe.

Fashion and the grand sentiment of gala were ruling the technique of the art of painting, by the side of devotional and classical association. The sentiment of parlour and tavern was translated by Fleming and Hollander into picture truth. In the wide stretches of the Netherlands were shore and sea, and specially air vision indoor and outdoor. In portraiture and landscape the Flemish-Dutch school of realists were painters of air from 1600 to 1670. The great magician was Rembrandt, able to conjure with the textures of light and darkness and to figure thereby not merely natural aspects but the problems of human individuality. The shadow mystery of his world was progenitor of much that in modern painter's art has become orthodoxy.

A painter too of air and light contemporary in the Spaniard Velázquez, whom the Renaissance had bred with the Flemish sense of adventure. Sensitive to the visual and subtle perspective of mutual values, he staged figures and objects in space—accepting the eye-focus as the interpreter of visible relations and reactions. Another outstanding master of the aerial scholarship was the French painter Claude Lorraine, who avowedly went to Rome to found his radiant vision on the landscape of the Roman campagna and the adjacent hills and coasts. The Poussin brothers beside him added to classical composition an impressionist figuring of sacred and profane images. Such were new scholarships of art outside the Rococo currency of the Colbert workshops. Then came the art engraver of the latter part of the 18th century with his golden age on the skirts of the traditions of the cinquecento. At first the great masters of Italian and then of Dutch painting were circulated in black and white in a way their original work had not contemplated. Soon in many industrious crafts, draughtsmen of the 17th and 18th centuries discovered tone-qualities and rendered black and white in the full body of mezzotint or in refinements of line texture such as copper engraving achieves. The vast widening of the picture field for domestic walls or for illustrative connoisseurship made the dawning of the modern period; but there was a setting, too, of much

of that sense of dedication that belonged to themes that had been those of religious and classic scholarship. It was symptomatic of the cycle of art, that in breaking through its banks the fine art of painting ran afield into shallows.

The 18th century era for English painting was to mature in the new horizons of pictorial adventure. The aristocratic portraiture of Reynolds and Gainsborough had been those of close allegiance to the tradition of the Fleming Van Dyck, who, the immediate pupil of Rubens, had himself drawn from the Venetians. Gainsborough and Wilson, too, English pastoral landscapists, were of the Claude school. But Hogarth proclaimed himself a rebel spirit, with the petulant assertion that the English world was to his hand to give him picture sense uncommitted to classic prescriptions—with no Olympian serenity to gloss a "Cheapside" medley or a "Shrimp Girl's" portrait. Then, too, in humble guise the typographical illustrator, for the pride of country gentlemen's seats, drew and coloured landscape settings to architectural views. But from this low estate the English water colourist was to rise to esteem; and though his place in the English academy was denied him, yet by the end of the 18th century great masters, like Crome and Constable, were oil and water painters both and it was water-colour artistry that carried Turner into acknowledged pre-eminence as a great modern master of fine art.

In Europe, eclectics of the 17th and 18th centuries had arisen outside the main Italian traditions; Carpaccio, Tiepolo, Canale and Longhi, errant stars rising and setting in the twilight of the Venetian decadence; Piranesi, a Roman etcher had a mystic sense of horror; his contemporary Blake in England toned visions of sanctified joy, toned to meek expressions of line and colour. In Spain the forerunner, initiate to the mystic significance of the modern cult was Goya, at once impressionist and hypnotic, "smearing his canvas with paint as a mason plasters his wall," a composer of the "Caprices" and "Misères de la Guerre" with the protesting energy of a French Revolutionist.

The antique graces of the old tradition still haunted the shrine of art, and in the latest years of the century we see a symptomatic return to severer principles and purer lines of scholarship from the Baroque and the Rococo. The pure and rhythmic grace of the English Flaxman in its sense of classic design was scarcely sculpture. In Italy came the over-honeyed accomplishments of Canova and his school; and with scarcely robust fibre were the statue works of the Norwegian, Thorwaldsen, practising in Rome; in France were graphic appreciations of classic virtue as read in Livy; in England the 19th century opened with a mild classicism and much pastoral and idyllic work of agreeable but shallow elegance; and the Nazarene school of German painting expended itself in a religious expression of singular insipidity. For French painting, however, the classic movement with roots in the associations of the French Revolution and attitudinizing as Roman virtue obtained a technical reality of picture force in David. There were, too, an accomplished purity and sweetness in Prud'hon's "nude" idylls. But the last and truest Classic of France, Ingres, who was at the same time in portraiture a modern realist, painted on into the romantic era. With Géricault and Delacroix, romance had its literary associations rampant for two generations; but by side of them, French landscape painting had got inspiration from the English Constable. Thus in the second quarter of the 19th century the curtain was being lifted for the drama of creative progress that was to be staged for French and English art.

Modern Aspects of Art and Craft.—The 19th century was seeking its *vision* of fine art in the association of painting quality with representative mimicry. The title artist had become the monopoly of the picture-making class committed to the figuring of nature; the architect was accounted just a draughtsman of style—and sculptors might shape and carve as nude model reproducers. In literary use the word "art" came to be accepted for what is put into a frame or hung in an exhibition. As a prophet of imitative reality the art critic established his reputation. Europe recovered its power to breed artists in academies when word-power stocked studios; in architecture the battle of style was fought between the religious and the pagan; scientifically the Greek revival read itself into porticoed churches and pillared rail-

way stations; garden landscapes were primed with pepper-box "Parthenons"; *national* taste protested itself romantic in the Elizabethan lodge and the castellated *picturesque*—and Christian faith materialized in sham Gothic and in clearing out 18th century galleries and pews from historic churches. In literature England and the Continent were founding the "romantic" of history and the "wild" of nature, and for two generations Victorian picture habit sought pictorial success in tags of sentiment and took poetic description as accredited art material. In period furniture arts and crafts revived an auctioneer's aptitude for descriptive title, and found credit in affected reproduction of the antique. The popularity of the Gothic movement of church revival may be said to have baptized the pre-Raphaelite coterie of painters. But with Ruskin's benison came the rejection of much time-honoured science of academic composition and brush handling; and there was new confirmation of the painter's colour-sense in the pictorial *vision* reforming itself. Victorian art had an era of creative abundance with the slick summaries of Millais, and the stark realism of Ford Madox Brown; in the over-studied archaeology of Holman Hunt as in the poetry and impassioned mediaevalism of Rossetti and Burne-Jones; equally in Orchardson's historical and social occasions and in Whistler's "Nocturnes" or Albert Moore's mannequins—in fact, picture poetry stormed art as it had literature. There was novelette absorption, too, of both sculpture and painting in France; in the *Salon* exhibitions and the *place* and *boulevard* pieces of Carpeaux and Dalon. We have Bartholomé in his procession of the dead entering the tomb staged as a Danesque masterpiece; Rodin working stone or bronze into textured poems—as psychical occasions rendered, with the metre and terseness of a quatrain. Though an ugly philosophy has distorted art in some continental schools we have had French caricature and English humour in *black and white* playing its part in social morality. Daumier, and the woodcut illustrators of the English '60s and their successors cannot all be accused of Freudian tenets.

Still the French experimenters were shifting all the practical tenets that had been gospel for the painting arts. The craft vision of modern art-workers promulgated as science plays for the literary stage. Writing in the 11th edition of the *Encyclopædia Britannica*, Sir Sidney Colvin said: "The movements of the Impressionists, the Luminists, the Neo-Impressionists, the Post Impressionists and Cubists, initiated in Paris, have been eagerly adopted and absorbed, or angrily controverted and denounced, or simply neglected and ignored according to the literary equipment of groups of artists and fashions of critics; there has been a vast amount of heterogeneous, hurried, confident and clamant innovating activity in this direction and in that, much of it perhaps doomed to futility in the ages of posterity but at any rate there has not been stagnation."

Written 25 years ago this should be supplemented by a further analysis of the 20th century aspects of art and craft. Much of the hope that Morris and his coadjutors introduced into craft has been drowned in the increasing industrial flood. Are we marking time for some new values of fine art to take their place in the social system? Perhaps so! But the associations of education are at present confining capacity to commercial specialities of knowledge, and as they have done so vocation and profession have grown neglectful of the universal issues. Learning has become fitted into grooves, running in which, craft—whether as labour or commerce is regardless of common appreciations, and only half educated for the practical purposes of life. If in such words, also, we rank the present output of all the fine arts, we necessarily accept as sponsor for it the social revolution of the 20th century which is rapidly bringing the whole world into a single community, and making fine art an individual pursuit, ceasing with the artist. (See ART; AESTHETICS; ARCHITECTURE; PAINTING; SCULPTURE; and kindred articles.)

In the writing of this article some use has been made of the article written by the late Sir Sidney Colvin for the 11th edition of the *Encyclopædia Britannica*. (E. S. P.)

FINE COTTON SPINNERS' AND DOUBLERS' ASSOCIATION, LTD. This British combination of com-

panies and firms engaged in spinning the fine Sea Island and Egyptian cottons, and in doubling yarns made from those and other staples of cotton was formed in 1898 with a capital of £6,000,000, which had grown in 1928, to a capital of £11,100,000. In addition to cotton spinning and weaving, the Association has large interests in cotton plantations and coal-mines, and in bleaching, dyeing and rope-making works.

The businesses amalgamated in 1898 were 31 in number, and further affiliations had by 1928 brought over 50 businesses within its scope, owning 3,279,000 spinning spindles and 989,500 doubling spindles. The number of workpeople employed is about 27,000. The Association has become the chief factor in the markets of the world for fine-spun yarns, especially those which are known as combed qualities; in 1928 its average yearly output was returned at about 75,000,000 lb. of yarn, which was exported to all parts of the world.

It has been the principle of the Association from the start to preserve the identity of the old established firms whose interests it amalgamated; they trade under their old names, use their old marks and maintain their individual reputations. (L. C. M.)

FINFOOT, the name applied to members of an interesting family of birds (Heliornithidae) of grebe-like form, allied most closely to the rails (Rallidae) and inhabiting various parts of the Old World and South America. (See ORNITHOLOGY.)

FINGAL'S CAVE. A famous cave situated on the southern coast of Staffa, an island of the Inner Hebrides. It was discovered in 1772 by Sir Joseph Banks and is of singular beauty. The cave is 227 ft. long and 42 ft. wide, each side being lined with a series of pillars. It is the haunt of the sea birds and seals of the locality. See STAFFA.

FINGER, one of the five members with which the hand is terminated, a digit; sometimes the word is restricted to the four digits other than the thumb. (See SKELETON: *Appendicular*.)

FINGER-AND-TOE, CLUB ROOT or ANBURY, a destructive plant-disease due to an organism known botanically as *Plasmiodiophora Brassicae*, which attacks cabbages, turnips, radishes and other cultivated and wild members of the family Cruciferae. It is one of the so-called slime-fungi (Myxomycetes or Mycetozoa). The presence of the disease is indicated by nodules or warty outgrowths on the root, which sometimes becomes much swollen and ultimately rots, emitting an unpleasant smell. The disease is contracted from spores present in the soil, which give rise to motile germs which enter the root. The parasite develops within the living cells of the plant, forming a glairy mass of living material known as the *plasmodium*, the form of which alters from time to time. The cells which have been attacked increase enormously in size and the disease spreads from cell to cell. Ultimately the plasmodium becomes resolved into numerous minute round spores which, on the decay of the root, are set free in the soil. The disease is more frequent in acid soils. A good dressing of lime (3-4 tons per acre) is thus useful in reducing or stopping the disease. It is important that diseased plants should be burned and not fed to animals as the spores can pass in a living state into the manure.

FINGERING, in music, the method of using the fingers in order to facilitate execution on a keyed, stringed, or wind instrument. In the case of keyed instruments, the evolution of the keyboard—which originally consisted of keys from four to six inches wide—has necessitated corresponding changes in the system of fingering employed. Thus for a very long period the thumb was never used at all, and the little finger scarcely more often. Gradually, however, a recognized system developed. J. S. Bach introduced the free use of both thumb and little finger, being one of the first to put the whole matter on a scientific and well thought-out basis, although the system which served its purpose has, with the ever increasing demands of pianoforte technique, undergone extensive further developments since his time.

In the case of stringed instruments, such as the violin and violoncello, the fingers are placed in certain positions on the strings according to the note required, while similarly, in the case of wind instruments, the disposition of the fingers as they close the holes or press down the keys is all-important.

RECORDING FINGERPRINTS FOR IDENTIFICATION

Photograph in centre shows method of recording fingerprints. Facsimile records are shown on either side. In making the record the thumb and fingers are pressed separately on an inked surface, then on spaces indicated on the identification card. Classification of impressions according to shape and contours and the number of the ridges has reached a highly developed technique. The value of fingerprints for purposes of identification rests upon the theory put forward by J. E. Purkinje in the early 19th century, and later established by Sir Francis Galton, of the *persistence* throughout the life of an individual of the shape or contour of his fingertips. In many passport departments, labour offices, military and police organizations, and other branches of government, fingerprint records have been adopted as a means of identification.

FINGER NUMERALS. The absence of inexpensive material upon which to write, cheap paper being a recent invention, led most early peoples to represent numbers by positions of the fingers, as is done by deaf mutes to-day. The use of such symbols has survived until modern times, particularly in international trade in the Orient. In the system inherited from the Greeks and Romans small numbers were usually represented on the left hand, the right hand being used for hundreds. When Juvenal wrote (*Satire X.*), "Happy is he indeed who has postponed the hour of his death so long and finally numbers his years upon his right hand," he referred to one who lives to be more than 100 years old. The illustration shows the finger symbolism as it was practiced in the middle ages.

The finger numerals are related to the finger computations in use in the middle ages, referred to in various early printed books and still familiar in certain parts of the world. The operation of multiplication was the one in which they played the most important part. The purpose was to avoid the learning of the multiplication table as far as 10×10 . For example, to multiply 8 by 6, turn down 8—5 fingers on one hand and 6—5 on the other. There are then 3 turned down and 2 standing on one hand and 1 turned down and 4 standing on the other. Add the fingers down ($3+1=4$) and multiply those standing ($2 \times 4=8$), and the result is 4 tens + 8 units, or 48; that is, in terms of mathematics, $ab = [(a-5) + (b-5)]10 + (10-a)(10-b)$. Numerous variants of the plan were in use, some having been brought to Europe from the Arab schools. (D. E. S.)

FINGER-PRINTS. The use of finger-prints as a system of identification is of very ancient origin, and was known from the earliest days in the East when the impression of his thumb was the monarch's sign-manual. A relic of this practice is still preserved in the formal confirmation of a legal document by "delivering" it as one's "act and deed." The permanent character of the finger-print was first put forward scientifically in 1823 by J. E. Purkinje, an eminent professor of physiology, who read a paper before the University of Breslau, adducing nine standard types of impressions and advocating a system of classification which attracted no great attention. Bewick, the English draughtsman, struck with the delicate qualities of the lineation, made engravings of the impression of two of his finger-tips and used them as signatures for his work. Sir Francis Galton, who laboured to introduce identification by finger-prints, points out that they were proposed for the identification of Chinese immigrants when registering their arrival in the United States. In India, Sir William Herschel desired to use finger-prints in the courts of the Hugli district to prevent false personation and fix the identity upon the executants of documents. The Bengal police under the administration of Sir E. R. Henry, afterwards chief commissioner of the London metropolitan police, usefully adopted finger-prints for the detection of crime, an example followed in many public departments in India.

The prints depend upon a peculiarity seen in the human hand and to some extent in the human foot. The skin is traversed in all directions by creases and ridges, which are ineradicable and show no change from childhood to extreme old age. The persistence of the markings of the finger-tips has been proved beyond all question, and this universally accepted quality has been the basis of the present system of identification. The impressions, when examined, show that the ridges appear in certain fixed patterns, from which an alphabet of signs or a system of notation has been arrived at for convenience of record. As the result of much experiment a fourfold scheme of classification has been evolved, and the various types employed are styled "arches," "loops," "whorls" and "composites." There are subclasses, and all

are perfectly distinguishable by an expert, who can describe each by its particular symbol in the code arranged, so that the whole "print" can be read as a distinct and separate expression.

One of the first methods of identification was the adoption of anthropometry (*q.v.*), which was invented by the French savant, A. Bertillon. The reasons that led to its general supersession may be summed up in its costliness, the demand for superior skill in subordinate agents and the liability to errors not easy to trace and correct. A still more potent reason remained, the comparative failure of results. It was found in the first four years of its use in England and Wales that an almost inappreciable number of identifications were effected by the anthropometric system; but in 1901 it was supplemented by the use of "finger prints," and this method of identification has proved an unqualified success.

The record of finger prints in England and Wales is kept by the Metropolitan police at New Scotland Yard. The advantages of the record system need not be emphasized. By its means identification is prompt, inevitable and absolutely accurate. By forwarding the finger prints of all criminal prisoners to New Scotland Yard, their antecedents are established beyond all hesitation.

Authority for taking finger-prints in England is given by the Penal Servitude Act 1891, which permits the secretary of State to make regulations as to the measuring of all prisoners who may for the time being be confined in any prison. Regulations have been made from time to time under that statute and a criminal prisoner can be measured at any time during imprisonment, which includes taking his finger-prints. An untried criminal prisoner while in prison cannot have his finger-prints taken save by the order of the secretary of State, or upon an application made by a superintendent of police approved by a justice of the peace or in the metropolis by the commissioner or assistant commissioner. Finger-prints may lawfully be taken at any time by consent, but if an untried prisoner objects and it becomes necessary to use force there must be confirmation by the secretary of State or the commissioner or assistant commissioner. Where, however, an untried prisoner who has not been previously convicted is discharged or acquitted, all finger-prints taken must be forthwith destroyed or handed over to the prisoner himself. Identity may be proved by means of finger-prints, and such evidence can be given by an expert on this subject.

FINGOES, a collective name applied to a number of Bantu-speaking tribes who formerly inhabited the greater part of Natal, but most of whom now live scattered about in the Eastern Province and Native Territories of the Cape. The best-known are the amaBele, amaHlubi and amaZizi, but they include many others who were broken up and dispersed in the great inter-tribal wars at the beginning of the 19th century. The name is derived from *amaFengu*, "wanderers." Culturally they belong to the eastern division of Southern Bantu (*see SOUTH AFRICA: Ethnology*), but their tribal organization has been almost completely disintegrated, and they have advanced in the adoption of European culture.

FINIAL, in architecture, the decorative upper termination of a pinnacle, gable end, buttress, canopy or spire; especially in the Romanesque and Gothic styles. It usually consists of a vertical pointed central element surrounded by four outcurving leaves or scrolls. When the form it decorates has crockets (*q.v.*) the finial may be formed of four or more crockets surrounding the central uprights. Finials in the form of candelabrum shafts occur frequently in early Renaissance work. The term is also applied loosely to any small pinnacle, knob or other decorative feature terminating a verticle motive (*see EPI*). (*See illustration, p. 250.*)

FINIGUERRA, MASO (*i.e.*, TOMMASO) (1426-1464), Florentine goldsmith, draughtsman and engraver, was born in March 1426 in Sta Lucia d'Ognissanti and died in Dec. 1464. He was the son of Antonio, and grandson of Tommaso Finiguerra or Finiguerri, goldsmiths of Florence, and was brought up to this profession, becoming early distinguished for his work in niello. In 1457 he was in partnership with Piero di Bartolommeo di Sali and the great Antonio Pollaiuolo, when they received an order for a pair of silver candlesticks for the church of San Jacopo at Pistoia. In 1463 Finiguerra drew cartoons for five or more figures

EXAMPLES OF VARIOUS TYPES OF FINIALS

for the sacristy of the duomo, which was being decorated in wood inlay by a group of artists with Giuliano da Maiano at their head. He also worked under Ghiberti on the gates of the baptistery.

Vasari erroneously represents Maso Finiguerra as having been the first inventor of the art of engraving (using that word in its popular sense of taking impressions on paper from designs engraved on metal plates). In the last years of the 18th century Vasari's account of Finiguerra's invention was held to have received a decisive and startling confirmation. There was in the baptistery at Florence (now in the Bargello) a 15th century niello pax of the Coronation of the Virgin. The Abate Gori, a connoisseur of the mid-century, had claimed this conjecturally for the work of Finiguerra; a later virtuoso, the Abate Zani, discovered first, in the collection of Count Seratti at Leghorn, a sulphur cast from the same niello (this cast is now in the British Museum), and then, in the National library at Paris, a paper impression corresponding to both. This he proclaimed was proof positive of Vasari's accuracy.

Zani's famous discovery is now discredited among serious students. It has been proved that the art of printing from engraved copper-plates had been known in Germany, and probably in Italy also, for years before the date of Finiguerra's alleged invention. Further, Maso's pax for the baptistery, if Cellini is to be trusted, represented not a Coronation of the Virgin but a Crucifixion, whose recorded weight does not agree with that of the pax claimed by Gori and Zani to be his. Again all records agree in representing Finiguerra as a close associate of Antonio Pollaiuolo. Nothing is more unlike their special style than the style of the Coronation pax, the designer of which must obviously have been trained in quite a different school, namely, that of Filippo Lippi. So this identification has to be abandoned. The only fully authenticated specimens of Finiguerra's work which exist are the above-mentioned tarsia figures, over half life-size, executed from his cartoons for the sacristy of the duomo. But his hand has lately been conjecturally recognized in a set of drawings of the school of Pollaiuolo at the Uffizi, some of which are inscribed "Maso Finiguerra" in a 17th century writing, probably that of Baldinucci; and in a very curious and important book of nearly 100 drawings by the same hand, acquired in 1888 for the British Museum. The hand is that of a draughtsman of the school of Pollaiuolo, some of whose drawings bear an ancient attribution to Finiguerra, while all agree with what is otherwise known of him, and one or two are exactly repeated in extant works of niello, the craft which was peculiarly his own; others being intimately related to the earliest

or all but the earliest works of Florentine engraving, the kindred craft which tradition avers him to have practised, and which Vasari erroneously believed him to have invented. Surely, it has been argued, this draughtsman must be no other than Finiguerra.

(1884); and for a full discussion of the whole question, Sidney Colvin, *A Florentine Picture Chronicle* (1898); C. Lewis Hind, *Catalogue of Early Italian Engravings in the British Museum* (1910).

FINING, a process for the clarification of liquors such as wine and beer, generally consisting of a solution of isinglass or a solution of tartaric or sulphurous acid. In the fining of wine, gelatin, or in the case of high-class red wines, white of egg is employed. After these have been added and the beer or wine well rolled, the fining matter subsides and is drained off carrying with it the suspended matters which cause turbidity. See BREWING and WINE.

FINISHING: see CLOTH FINISHING.

FINISTÈRE, the most western department of France, formed from part of the old province of Brittany. Pop. (1926) 753,702. Area, 2,713 square miles. It is bounded W. and S. by the Atlantic Ocean, E. by the departments of Côtes-du-Nord and Morbihan, and N. by the English Channel.

Finistère is the west end of the worn down ancient fold region, axes of which still emerge slightly as the Monts d'Arrée (1,282 ft.) in the north and Montagnes Noires in the south. These run east and west, with the Aulne basin between them. Small streams flow north from the Monts d'Arrée and south from the Montagnes Noires. The Aulne and Elorn, and the other streams in lesser degree, have estuaries due to coastal sinking, and these estuaries form the harbour of Brest and other navigable entries. Off the promontories prolonging the Monts d'Arrée are the Ushant islands and off that prolonging the Montagnes Noires the Îles de Sein in the south, with Batz off the north coast and many others. Between islands and mainland are famous tide races which make navigation difficult. The coasts are often steep and rocky.

The climate is oceanic, average temperature 52°, rainfall heavy. Though more than a third of the department is covered by heath, waste land and forest, it produces oats, wheat, buckwheat, rye and barley. The neighbourhood of Roscoff and the borders of the Brest roadstead are extremely fertile and yield large quantities of asparagus, artichokes and onions, besides melons and other fruits. The cider apple is abundant. Hemp and flax are also grown. The farm and dairy produce is plentiful, and cattle and horses are largely bred. Honey and wax are produced. The great pilchard fishery makes this department a nursery of seamen for the French navy. Coal, though found in Finistère, is not mined; there are quarries of granite, slate, potter's clay, etc. The lead mines of Poullaouen and Huelgoat, which long yielded silver, are no longer worked. The preparation of sardines is carried on on a large scale at several coast-towns. The manufactures include ropes, agricultural implements, paper, leather, earthenware, soap, candles and fertilizers and chemicals derived from seaweed. Brest has important foundries and engineering works; and shipbuilding is carried on there and at other seaports. Brest and Morlaix are the most important commercial ports. Trade is in fish, vegetables and fruit. Coal is the chief import. The department is served by the Orléans and Ouest-État railways. The canal from Nantes to Brest traverses the department.

Finistère is divided into the following arrondissements of Brest, Châteaulin, Morlaix and Quimper (43 cantons, 299 communes), the town of Quimper being the capital of the department and the seat of a bishopric. The north of the department belongs to the region of the X. army corps (Rennes), and the south to the region of the XI. army corps (Nantes) and the whole to the archiepiscopal province and académie (educational division) of Rennes, where its court of appeal is also situated.

The more important places are the ports of Quimper, Brest, Morlaix, Quimperlé, Douarnenez, Concarneau, Roscoff and, inland, Landerneau and Châteaulin. Finistère abounds in menhirs

and other megalithic monuments, of which those of Penmarc'h, Plouarzel and Crozon are most noted. The two religious structures characteristic of Brittany—calvaries and ossuaries—are frequently met with, e.g., the calvaries of Plougastel-Daoulas, Pleyben, St. Thégonnec (17th century), and Guimiliau (16th century), and the ossuaries of Sizun and St. Thégonnec (16th century) and Guimiliau (17th century). Daoulas has the remains of a fine Romanesque church and cloister. Locronan and St. Jean du Doigt have interesting churches and are among many centres of famous folk ceremonies called "pardons." St. Pol de Léon has a fine granite Gothic cathedral. Kerjean has a large 16th century château.

FINITE DIFFERENCES: see CALCULUS OF DIFFERENCES.

FINLAND (*Suomen Tasavalta*), "the land of a thousand lakes," formerly for a time a grand duchy under Russian sovereignty, but independent since Dec. 6, 1917, extends from 59° 48'

AN OLD WOODEN CHURCH DATING FROM 1758, PARISH OF KEURUU, IN THE INTERIOR

to 70° 6' N. and 19° 2' to 32° 48' E. Its extreme length is 700 m. from north to south. Finland is bordered on the north by Norwegian Lapland, on the east by Russia, on the south by the Gulf of Finland and on the west by the Gulf of Bothnia and Sweden. It includes part of Russian Lapland. In the south-west it is skirted by the numerous rocky Åland islands (*q.v.*). By the treaty of Dorpat, Oct. 14, 1920, Soviet Russia ceded the Petsamo district (68° 5'–69° 57' N. and 28° 25'–32° 20' E.) thus giving Finland access to the ice-free fjord of Petsamo and the Arctic Ocean. This district is as yet connected with Finland by road transport only.

Geography.—It has an area of 149,588 sq.m., of which about 35% is forest, 11% lakes, 3% arable and 5% grass land. Among the largest lakes are: Ladoga, the largest in Europe, of which the northern half belongs to Finland; Saima, three and a half times larger than Lake Lemman, whose outlet, the Vuoksen, flows into Lake Ladoga, forming the mighty Imatra rapids; lakes Kalla, Päjäne, Nasi-jarvi, Pyhä-jarvi, Enare, Torneå, Hauki, etc. The surface of the country is tableland rising 400 to 600 ft. above sea level, with elevations reaching 2,000 feet. In the extreme north-west, 4,115 ft. is attained in the Halditjokko. The coastline (1,646 km.) is generally low. The rivers are unimportant, the chief being the Muonio which flows between Finland and Sweden, the Kemi and the Uleå, which is navigable throughout.

In its geological structure Finland is closely related to the Scandinavian Peninsula, showing granite and archæan rocks covered with glacial and post-glacial deposits (partly of lacustrine and partly of marine origin).

The climate of Finland is rigorous, but in the west and south-west, owing to the moderating influence of the Baltic, less severe than farther east in corresponding latitudes. Everywhere, especially in the interior, the winter lasts very long; the summer from two to two and a half months. Spring and autumn are of short duration.

Flora and Fauna.—Finnish botanists have divided the country into 28 different areas, giving the numbers of phanerogam species for each. These vary from 318 to 400 species in Lapland, 508 to 651 in Karelia, to 772 in Finland proper. The chief forest trees are: the Scotch fir (*Pinus sylvestris*), the fir (*Picea excelsa*);

two species of birch (*B. verrucosa* and *B. odorata*); birch-bush (*B. nana*); two species of *Alnus* (*glutinosa* and *incana*). The oak (*Q. pedunculata*) grows only on the south coast. The Siberian larch was introduced in culture in the 18th century. The forest area comprises 62,429,000 ac., of which 40% is State-owned. In 1926, the lumber cut by the Department of Forestry was valued at 61,600,000 marks, the erect timber sold was valued at 97,900,000 marks, the lumber sold from State sawmills at 77,800,000 marks.

Agriculture, Industries, Shipping, etc.—Owing to the rigorous climate and the limited cultivable area, Finland's home supply of agricultural products falls far short of the demand. The principal items in the order of their importance are: hay, cultivated and natural, potatoes, oats, rye, barley, wheat, *i.e.*, a total harvest and to the value of approximately five million marks. Live-stock: horses number 399,998; cattle 1,860,479; sheep 1,413,697; pigs 390,535; goats 11,076. The output of butter totals 20,060,000 kg.; of cheese 5,290,000 kg. The number of dairies is 596, giving a butter production of 20,062 tons.

Finland had, in 1926, 3,526 large factories, employing an aggregate of 149,367 workers, and yielding 10,935,000 marks. The chief industries in the order of their importance are: wood industries, paper, iron and mechanical works, textiles, leather, tobacco, graphic arts, electricity, water and gas, chemicals. There were 513 sawmills with 97 water motors, 537 steam, 26 oil and gas and 1,994 electric motors.

The mercantile marine of Finland on Jan. 1, 1927, aggregated 4,930 vessels of 477,329 net registered tons. There were two airlines: Helsinki–Stockholm and Helsinki–Reval, carrying, in 1926, 3,218 passengers and 52,661 kg. goods and mail.

The numerous lakes are utilized freely for transport, and joined by short canals, so as to constitute continuous waterways. About 60,000 vessels pass along the canals, and about 15,000 timber-rafts; the net revenue from the canals amounting to about 5,000,000 marks. There are approximately 15,700 m. of high roads and 16,000 m. of secondary roads. The first railway in Finland was completed in 1862—the Helsinki–Häme line, about 80 m. in length. By 1927 there were 2,886 m. of railway, all but 160 m. State-owned. The gauge is 4-9 feet. The traffic (in 1926) was 22,000,000 passengers and 10,200,000 tons of goods carried, representing a net revenue of 129,873,000 marks. Connection

with the Swedish railways has been established since the World War. Telegraph offices number 2,811, there being 14,170 m. of telegraph and 5,264 m. of telephone, all State-owned.

Population.—The population of Finland in 1926 amounted to 3,558,059, of whom 17.1% lived in towns, the remainder in country districts. Classification according to language is as follows: Finnish 88.7%, Swedish 11.0%, others 0.3%; according to religion: Protestant 97%, Greek Orthodox 1.7%, Roman Catholic 0.02%, others 1.28%; according to occupation: agriculture 65%, industry 15%, transport 3%, commerce 3%, public administration 2%, professions

COSTUME OF A PEASANT WOMAN (LEFT). A TYPE OF A "NATIONAL" COSTUME (RIGHT)

2%, miscellaneous 10%. In 1926, the birth-rate was 21.7 per 1,000; the death-rate 13.4 per 1,000. This meant an excess of births by 29,349 per annum.

The leading cities are: Helsinki (Helsingfors), capital of Finland and capital of the province of Uusimaa, principal seaport, 215,829 inhabitants; Turku (Åbo), capital of the province of Turku-Pori (Åbo-Björneborg), university town of 61,664; Tampere (Tammerfors), principal manufacturing town, 52,394; Viipuri (Viborg), capital of the province of the same name, 48,990; Vaasa (Vasa), 24,218; Oulu (Uleåborg), 23,020; Kuopio

22,716; Pori 17,576; Kotka 14,768; Tavastehus 5,545.

Education.—Education in Finland is both cheap and thorough, and it is somewhat closely modelled on the German system. There are three universities, of which the premier was founded at Turku in 1640, but transferred to Helsinki in 1827. It has a teaching body of 272 professors and 2,946 students (838 women). Turku was provided, in 1919, with a Swedo-Finnish academy, which, three years later, was raised to the status of a national university. Further, a technical high-school and two commercial schools are established in Helsinki. Throughout the country there are 181 secondary schools with a teaching staff of 2,926 and 44,643 pupils. Primary education, public and denominational, has a teaching staff of 11,591, and 426,169 pupils. Compulsory education has only existed since 1921.

See the *Annuaire Statistique de Finlande; Constitution de la Finlande* (1920); *The Republic of Finland: an Economic and Financial Survey* (1920); *Atlas de Finlande* (3 vols. 1911). The above are published by the government at Helsinki. See also *Bulletin of the Soc. Geographique de Finlande* (Helsinki); Th. Homen, *East Carelia and Kola Capmark* (Helsinki, 1921); K. W. Hopper, *Finnish Harbours* (Helsinki, 1922).

(W. L. B.)

Defence.—The detachment of Finland from Russia dates from the World War of 1914–18. Finland has land frontiers with Soviet Russia and with Sweden extending for 3,039km., and a coast-line of 1,646km. In October 1920 a treaty was contracted with Soviet Russia which prevents the construction of fortifications on certain islands, or their use for any military purpose (Treaty Series, League of Nations, vol. 3, No. 91). In 1921 Finland undertook not to fortify the Aaland islands (*ibid.* vol. 9, No. 255).

All male Finnish citizens are liable for military service in war from Jan. 1 of the year in which their 17th birthday falls until the completion of their 52nd year. Service in peace in the active army begins in the year in which their 21st birthday falls. Total service is for 35 years. Those of ages from 17 to 21 form the 3rd class of the "Landwehr"; those conscripted at 21 join the active army, pass into the active army reserve at 22, and into the first class of the Landwehr from 29 to 52; others pass into the second class of the Landwehr from 21 to 52. The training at 21 to 22 is for 12 months in the infantry and for 15 months in cavalry, air force, artillery, technical troops, etc. Reservists attend occasional training.

The budget effective strength of the peace-army is about 28,000 including 1,500 officers and 450 officials. The army is organized in 3 divisions of all arms, one machine gun company being included in each division, a tank battalion in the 1st division, 2 cyclist battalions in the 2nd division, and one in the 3rd division. There is also a cavalry brigade, technical troops and coast artillery. Officers are trained at a cadet school at Helsingfors under the Ministry. The President of the Republic is Commander-in-Chief. He can delegate his powers to a general in war, and has a general to command the active army under him in peace, with a Chief of the General Staff and Ministry of Defence. There is a military Air Force of 5 squadrons, an aviation school and a recruit company. When Finland joined the League of Nations an establishment of 69 aeroplanes was approved by that body which reserved for consideration proposals for increasing this force.

See also League of Nations *Armaments Yearbook*, 1928.

(G. G. A.)

Navy.—The only naval force of Finland is a collection of patrol-boats (4), torpedo-boats (2), minelayers (4) and minesweepers (2).

ECONOMICS AND FINANCE

Until 1917, Russia remained a very considerable buyer of Finnish goods, but the revolution brought about a complete reversal of conditions, and trade with Finland became insignificant. After the World War, Finland, accordingly, had to shoulder the task not only of regaining her old markets in the West, but also of creating new markets to set off the loss of Russian trade. Similar difficulties were met in the import trade.

Imports and Exports.—The adjustment to the changed conditions was achieved with surprising rapidity, in spite of the unfavourable business conditions which prevailed on the leading

markets. It was temporarily helped by the declining tendency of the Finnish exchange, which in the autumn of 1921 brought quotations down to a bottom level.

	Exports.		Imports.	
	Value mill. Finnish marks.	Percentage of volume of 1913.	Value mill. Finnish marks.	Percentage of volume of 1913.
1913 . .	404.8	100.0	495.4	100.0
1919 . .	880.4	47.6	2,500.9	77.8
1920 . .	2,926.4	68.6	3,626.5	52.8
1921 . .	3,389.4	69.0	3,585.7	54.5
1922 . .	4,467.6	93.5	3,969.9	74.7
1923 . .	4,392.5	94.8	4,600.3	101.5
1924 . .	4,970.6	112.7	4,715.5	99.3
1925 . .	5,573.5	123.9	5,510.5	105.9
1926 . .	5,636.5	127.5	5,667.7	116.3

Great Britain took about 38% of Finnish exports in 1926. In the import trade the part played by Great Britain (13% in 1926), though considerable, is inferior to that of Germany (35% in 1926). The trade with Great Britain during recent years has gained ground when compared with pre-War conditions, but trade with Russia has not yet recovered. Timber products have long been of paramount importance in Finnish export trade, and timber exports after the War reached, and even exceeded, the record level of 1913. In 1926 the timber industry contributed about 56% of the total exports. The paper and pulp exports are second in importance only to the timber exports, the share of this industry in total exports amounting in 1926 to about 29%. Agricultural exports gradually revived, but the import of cereals, a very large item in Finnish foreign trade, showed some tendency to decline.

Currency.—When, at the end of 1917, Finland gained her independence, she had to cover the increased expenditure imposed by her new position as an independent state, and that incurred in the suppression of the Red rebellion in the spring of 1918. As the taxes could not be punctually collected, the government resorted to increased borrowing. Part of this demand for credit was met by means of new note issues by the State Bank.

During the course of the years 1919, 1920, and 1921 the Finnish exchange declined seriously. In the latter part of 1922 the Bank of Finland embarked on a policy of stabilizing the Finnish exchange in relation to the dollar, and since that date variations have been slight. At the end of 1925 the Finnish monetary system was put on a gold basis, the level of parity being approximately 193.23 Finnish marks to the £ sterling.

Finnish Monetary Statistics.

	Rates of exchange on New York. Par 5.18 mks. = 1 dollar.		Index of wholesale prices.
	Highest.	Lowest.	Annual average base 1913 = 100.
1921 . . .	80.50	28.00	1263
1922 . . .	54.50	35.25	1219
1924 . . .	40.44	39.70	1100
1925 . . .	39.70	39.70	1129
1926 . . .	39.70	39.70	1088

Banks.—The leading banking institutes are at present Nordiska Föreningsbanken, Kansallis Osake-Pankki, Helsingfors Aktiebank and Unionbanken, which at the end of 1926 held above 70% of the total home deposits of the 19 joint stock banks in existence. The note circulation of Finland's Bank, the bank of issue, at the end of 1926 amounted to 1,346,000,000 Finnish marks, backed by a gold reserve of 327,000,000 marks and foreign assets exceeding 1,000,000,000 marks.

National Budget.—The improved conditions of production and trade formed a firm basis for financial reorganization. Before the War the bulk of the Finnish State revenue was derived from customs duties and other indirect taxes and from the earnings of

government enterprises, mainly the railways. The chief change in finance since the World War has been the introduction of an income and property tax. The customs duties still form the main part of the state revenue, but direct taxes now yield about a quarter of the total tax revenue. The income from state enterprises is relatively less than before the World War. The public debt, foreign and internal, in Sept. 1927, was estimated at a sum equivalent to \$94,100,000. The debt is balanced by state forests, railways and other state property.

Tariff Policy.—The pre-War tariff might be characterized as a Protectionist one, but it granted practically no protection to grain-growing. Post-War legislation has provided agricultural protection and, with the elimination of the special facilities formerly existing between Russia and Finland, the grain duties now established were expected sensibly to influence agricultural conditions. The new policy made no radical change in the tariff on manufactured goods, but sought to promote a more scientific distribution of duties and to secure as large an income as possible to the state. But the revision of the tariff was not completed in 1927.

Social Legislation.—An active policy aiming at improving the position of the numerous landless agricultural population had been set on foot before the World War. After gaining her independence Finland adopted laws which with certain limitations gave tenants the opportunity of purchasing their holdings at a price below their value in the open market, and a large number of tenants have been turned into small owners. Recent social legislation further includes the adoption of an eight-hour day. Financial considerations have limited the scope of actual legislation for social insurance, but workmen's compensation for accidents has been put on a new and more comprehensive basis by legislation in 1917 and 1925. The co-operative movement has made considerable progress in Finland. (A. Mo.)

HISTORY

The Finns as a group under this name come into history at the beginning of the 8th century. They were brave and hardy colonists who defied the forces of nature, "Ukko" as god of the air, "Tapio" of the forests, "Ahti" of water, etc. But their repeated raids on the coast of Scandinavia, caused the Swedish king Eric IX. (St. Eric) to conquer the country in 1157, thus bringing it into contact with civilization. He left behind Henry, bishop of Uppsala (believed an Englishman) with priests and soldiers to complete the conversion. Henry was killed, but was afterwards canonized and, as St. Henry, became the patron saint of Finland. The country relapsed into paganism until, in 1209, another bishop and missionary, Thomas (also an Englishman), recommenced the work of St. Henry. He nearly succeeded in detaching Finland from Sweden and making it a province subject to the Pope. The famous Birger Jarl compelled the Tavastians, one of the subdivisions of Finlanders, to accept Christianity in 1249; Torkel Knutson conquered the Karelians in 1293 and built the castle of Viborg. Henceforth Finland became the cockpit of Northern Europe in the almost continuous struggle between Russia and Sweden which lasted until 1809.

Swedish Rule.—The Swedes spread civilization and accorded to the Finns the same civil rights as belonged to themselves. About 1528, Gustavus Vasa introduced the Reformed religion, and King John III. raised the country to the dignity of a grand-duchy. Gustavus Adolphus at the beginning of the 17th century established the Diet of Finland, composed of the four orders of the nobility, clergy, burghers and peasants. He and his successors did much for learning, but the country suffered terribly from war, famine and pestilence.

In 1710 Peter the Great set out to wrest Finland from Sweden, and six years later the whole country was in his power. Thousands perished in the wars of Charles XII., but by the Treaty of Nystadt in 1721 the Russians retained the province of Viborg, the eastern division of Finland. Twenty years later the Swedes attempted reconquest, but suffered disaster. In 1788 Gustavus III. confirmed

those "fundamental laws" which the Finns succeeded in maintaining against kings and tsars for over two centuries. Latin disappeared as the academic language, and Swedish was adopted. The same year war again broke out between Sweden and Russia, and was carried on for two years without result. In 1808, under Gustavus IV., peace was again broken, but this time the war ended by the cession to Russia in 1809 of the whole of Finland and the Åland islands.

Russian Rule.—Finland did not enter Russia as a conquered province. The emperor Alexander I. granted her a free constitution and fundamental laws, and she became a semi-independent grand-duchy with the emperor as grand-duke. A senate was created and a governor general named. The province of Viborg was reunited with Finland in 1811. Åbo remained the capital till 1821, when the seat of government was transferred to Helsingfors. The university was also transferred thither in 1827. The diet, which had not met for 56 years, was convoked by Alexander II. at Helsingfors in 1863; but it was only under his successor, Alexander III., that the Slavophil movement, with the motto "one law, one church, one tongue," acquired influence in official circles. Politics in Finland were complicated by the rivalry between the Swedish party, hitherto dominant, and the Finnish "nationalist" party which was asserting itself linguistically and politically.

First Period of Russification, 1899-1905.—Nicholas II., by the "February Manifesto" (Feb. 15, 1899) virtually abrogated the legislative power of the Finnish Diet. A new military law, practically amalgamating the Finnish with the Russian forces, followed in July 1901; Russian officials and the Russian language were foisted on Finland wherever possible, and in April 1903 the Russian governor, Gen. Bobrikov, was invested with dictatorial powers. To the Russian system of spies, domiciliary visits, illegal arrests, banishments and the suppression of newspapers, the Finns opposed a dogged resistance which culminated in the famous "national strike" of Nov. 1905. After six days the unconstitutional government—already much shaken by the events in Russia and Manchuria—capitulated. An imperial manifesto of Nov. 7, 1905, restored the *status quo ante* 1899. The new diet remodelled the constitution on the basis of universal suffrage, with freedom of the press, speech, meeting and association.

Second Period of Russification, 1908-14.—After "two glorious years of peace" and internal progress, the tsar peremptorily fixed an annual contribution in lieu of military service (Ukase of Oct. 7, 1909) and the Imperial Duma approved of the principle (Imperial law, Jan. 23, O.S., 1912). The Finnish Diet, though ready to compromise, was twice dissolved, and all the large measures of domestic reform which it had passed were never heard of again. Such was the fate of the bill for the prohibition of alcohol, of measures relating to the care of children, insurance, old-age pensions, education, public health, the betterment of the landless workers upon the soil. Civil marriages, however, were instituted, illegitimate children placed on a better basis, the principle of "equal pay for equal work" was applied in the teaching profession, in the printing trade and, in 1913, in the State service. The Duma alone considered itself competent to decide the questions affecting the interests of the Russian empire. Accordingly it passed the "Imperial Legislation Act" on June 30/17, 1910, amid shouts of "Finns Finlandiae." Two imperial laws were laid before the Diet which refused them both, and was dissolved. In one, the Duma affirmed the principle of an annual indemnity in lieu of service; in the other, full civil rights were accorded to temporary Russian residents in Finland. The last-named measure, apart from its injustice, caused the overlapping of two different codes of law. Judges resigned, high officials went into exile, every provisional governor left voluntarily or under compulsion. The country was ruled by a packed Senate, the Diet was peremptorily dismissed, the press censored. The Russification inflicted by the Duma was as oppressive as that imposed by the tsar.

The World War and the Russian Revolution.—Lt.-Gen. F. Seyn, the governor-general, supervised the harassing restrictions of liberty which the World War brought with it. Finland, protected by two systems of fortified lines, escaped invasion, but

the mercantile marine remained locked in the harbours of the Bothnian gulf. There being no leaks in the Allied blockade—as in Sweden and Denmark—the price of living rose by 25%. But industries connected with military supply attained unexampled prosperity. The Russians, sporadically anxious to please, abolished the annual military indemnity and merely imposed a 5% tax on property and mortgage. Finland naturally feared that a victorious Russia would again turn oppressor. Only some 2,000 volunteered for the Russian army. About the same number enlisted on the German side, ostensibly only for service on the eastern front.

Nicholas II. abdicated on March 15, 1917, and the Provisional Government restored representative government in Finland. The Russianized Senate was disbanded and a temporary body of 12 (half Social Democrats, half representing the bourgeoisie) assumed executive power. Stakovich became governor-general, Rodichev, a tried friend, secretary of state for Finland. The Socialist speaker of the Diet, M. Tokoi, was nominated president of the Senate; Kullervo Manner, of the same party, speaker of the Diet. But the propertied classes in Finland quailed before the rising power of the Social Democratic Party—orientated towards Russia. The intense industrial development had strengthened hooliganism, and the war had brought some 40,000 Russian refugees from food shortage and incipient riot. The Swedo-Finns aimed at complete independence, and the Finnish Government proclaimed that such was its policy. The Diet resolved that it alone was competent to pass and put into practice all laws in Finland relating to home affairs and finance. This law of July 18, 1917, reflected the standpoint of the Social Democratic majority which was ready to recognize Russia's supremacy in military matters and foreign policy. The deadlock which ensued, the dilatory Russian Provisional Government never succeeded in settling. The Finnish Diet passed *en bloc* all bills previously held up by the tsar, including the total prohibition of alcohol and the eight-hour day. Yet it failed to relieve the food-shortage which was due to the neglect of agriculture in the immediate preceding years. From March 1917 to Feb. 1918 repeated strikes threatened the existence of the nation. Meanwhile, the advent of the Bolsheviks to power in Oct. 1917 deepened the pro-Russian sympathies of the Social Democrats, while the Swedo-Finn and Finno-Finn propertied classes sought to cut adrift from a Russia which had no settled government. On Dec. 6, 1917, the Diet and the now bourgeois Senate drew up a declaration of independence which is held to mark the birth of Finnish freedom. The Bolsheviks, on Jan. 4, 1918, declared that the step conformed with their policy, whereupon Sweden and the other Scandinavian countries acknowledged the independence of Finland. France followed. The treaty of Brest Litovsk (March 3, 1918) confirmed Finland's independence, and four days later she concluded a treaty which made her Germany's ally and vassal. (See BREST LITOVSK, TREATIES OF.)

The Finnish Social Democrats, almost all Maximalists and anti-militarists, pinned their faith on the Muscovite connection to save the country from invasion. But the garrisons, starving and unpaid, banded themselves together as "Red Guards" (reinforced from Russia) and ransacked the country. A hurriedly organized White Army, under Baron Carl Gustav Emil Mannerheim, proved insufficient to maintain order. Sweden refused to help, but the Germans did not hesitate. They sent a composite division, initially some 12,000 strong, under Gen. Count Rüdiger von der Goltz, and held the Red forces in a successful action near Karis on April 6. This enabled Gen. Mannerheim to win the battle of Tammerfors, whereupon Goltz entered Helsingfors on April 14. Finally, the German victory over the Reds (April 30–May 2) at Lahti-Tavastehus contributed to Mannerheim's decisive victory near Viborg (April 28–29). But the cruelty of the Red insurrectionaries led to a White counter-terror. Some 15,000 men, women and children were slaughtered, and by June 27, 1918, 73,915 Red rebels, including 4,600 women, were prisoners of war.

The Diet, which met in June 1918, was moderate, since the Socialists who formed 46% of the electorate were excluded from the register. It authorized the Germanophil senator, Pehr Evind Svinhufud, to exercise the supreme power in so far as it had not

already been conferred on the Senate, which offered the crown to Prince Frederick Charles of Hesse, brother-in-law of the German emperor. Prince Charles accepted the crown, but never proceeded to Finland and the question was allowed to lapse.

The Germans pursued the ulterior object of securing Finnish military co-operation against the Murman railway, which was guarded by a British expeditionary force. The claim of the liberators upon the gratitude of the Finns was assuming the most peremptory forms known to diplomacy when, on July 18, the Allied offensive in the West diverted Germany's forces. Thus valuable time was gained until the Armistice of Nov. 11, 1918, orientated Finland towards the democratic régime associated with England and America. Svinhufud was succeeded on Dec. 12 by Mannerheim as regent, who formed a coalition government composed of six Republicans and six Monarchists. The German troops, in part mutinous, were conveyed back to Germany. In 1919 Mannerheim organized the "Skyddskorps" of 100,000 men to maintain order. In the general election of March 1, 80 Social Democrats, 42 Agrarians, 28 Coalitionists, 26 Progressives, 22 Swedes and 2 Christian Labour members were returned. The Agrarian party, composed of small land-owners, opposed the Swedish-speaking monarchist section. The Social Democrats lost 12 seats owing to the disfranchisement of 40,000 voters for participation in the Red revolt.

When, at the end of May 1919, the British 237th Brigade (of the expeditionary force under Maj.-Gen. Maynard's command) reached Lake Onega, Mannerheim offered co-operation in return for Petrozavodsk. The offer being declined, a Finnish volunteer force nevertheless assaulted the town, but without success. Again, at the close of the year, when the White Russian Gen. Yudenitch marched on Petrograd, Mannerheim sounded the Allies on Finnish intervention. He received no encouragement from Paris or London, nor from the Moderates at home.

Establishment of the Republic.—On June 17, 1919, the Finnish Diet established a republic. The new constitution came into force on July 17. There is a single chamber, the Diet, in which the sovereign power is embodied. The executive power is vested in a president who is chosen by 300 presidential electors nominated by the citizens. He ratifies new laws or withholds consent, dissolves the Diet, orders new elections and conducts foreign affairs. All his powers are exercisable through the ministers and his decisions have to be taken in the council of State consisting of 10 ministers, who are legally and politically responsible. There are nine departments for local government, closely following the linguistic distribution. Both Finnish and Swedish are official languages. On July 25, Prof. Kaarlo Juho Ståhlberg was chosen first president. A Coalition anti-Socialist Government under Erich held office till April 9, 1921. The Vennola Government, a coalition of Progressive and Agrarian parties, then came into power and passed the Amnesty bill. On May 6, 1919, Great Britain recognized the independence of Finland *de jure*.

A peace treaty was signed with Soviet Russia at Dorpat on Oct. 14, 1920. Pechenga was ceded to Finland, which thus obtained an outlet on the Arctic ocean. On Dec. 16, 1920, Finland was admitted as a member of the League of Nations. As such it claimed sovereignty over the Åland islands (*q.v.*) which was disputed by Sweden. In June 1921 the League of Nations decided in favour of Finland.

Despite the Treaty of Dorpat, relations with Soviet Russia did not improve. In Oct. 1921 the Karelians, racially allied to the Finns, revolted against Moscow, but the rising was crushed. The Karelian question, at the instance of Finland, occupied the League of Nations all through 1923. The Permanent Court of International Justice decided in July not to deal with this matter, as Russia was not a member of the League and might not recognize its competence. The Council of the League, however, determined that this view of the Permanent Court should not hinder a settlement, which resolve the Assembly of the League strongly supported. But the Commissar for Foreign Affairs, M. Chicherin, declared Karelia part of Soviet Russia. His argument had the support of the red battalions.

In these years, Finnish foreign policy remained in the hands

of Dr. R. Holsti, under successive administrations. In March 1922, this statesman signed at Warsaw an agreement with Estonia, Latvia and Poland "to observe benevolent neutrality towards any of the signatory states which might be attacked without provocation and to consult immediately with regard to subsequent steps to be taken." The Finnish Diet, in its spring session, refused to ratify this agreement, and Dr. Holsti relinquished office. The principle of policy enunciated upon this occasion by the Diet—the avoidance of treaty commitments of a military nature, continued to rule Finland's Baltic policy. On June 27, 1924, Finland signed bilateral conventions with Sweden, Norway and Denmark for compulsory arbitration.

Internal Policy.—The Karelian dispute reacted on Finnish internal politics. The long land-frontier made it impossible to keep out Russian propagandists and the discontent, thus fomented, threatened the economic recovery of the country. In May 1922 the Vennola administration was superseded by Professor Cajander's "Government of Officials," but it did not long outlive the general election held in July. The Social Democrats returned only 53 seats, while the Agrarians and the Union Party showed small gains. The Communists secured 27 seats.

In Nov. 1922, therefore, the Agrarians, who had held their ground, formed a Centre Government under Kyösti Kaalo, which passed the Religious Liberty Act, the Military Service bill and the "Lex Kaalo" which made provision for the landless population. In Oct. 1923 the Communist Party was suddenly dissolved, its newspapers were suppressed, and 25 of its parliamentary representatives imprisoned. But this stroke reduced the Diet to a rump, and the Kaalo Government resigned on the eve of the new elections in April 1924, handing over to Prof. Cajander's (second) "Government of Officials." The Social Democrats obtained 60 seats (+7), Communists 18 (−9), Agrarians 44 (−1), Union Party 23 (−2). On May 31, Prof. Lauri Ingman (Union Party) formed a Government. M. Lauri Relander was elected President on Feb. 16, 1925.

The Government of Professor Tulenheimo, in which the Union Party and the Agrarian Union were represented, took office on March 31, 1925. It had to pass the military and naval estimates, which represent approximately 17% of the national expenditure. The refusal of the Diet to sanction the programme of naval construction brought into office M. Kyösti Kaalo with the support of the Coalition and the Agrarian Parties. Holding only 82 seats in a Diet of 200, its legislative achievements were meagre. It survived until Nov. 23, when allegations were made in the Diet of illegal dealings between the Ministry of Defence and a Finnish ammunition factory. M. Tanner, after a prolonged crisis, succeeded on Dec. 11 in forming a purely Socialist Government. It had the support of the Progressive and Swedish Parties. On April 11, 1927, Hr. Irkonen, minister of the interior, resigned because he was accused of having spent money on the fisheries protection ship in excess of the amount sanctioned; the Government nevertheless carried the Amnesty bill by 96 votes against 94, and the last persons, still penalized for taking part in the revolution of 1918, 1,175 in all, regained their liberty and civil rights. The general election on July 2, resulted as follows: Swedish Party 24 (−1), Finnish Coalition 34 (−8), Progressives 10 (−7), Agrarians 52 (−8), Socialists 60 (same), Communists 20 (−2). The new diet met on Sept. 1 to pass the budget and, in particular, the increased army estimates. The double property tax was dropped. On Dec. 9, the Labour Government was defeated on the question of import duties on rye, and resigned. A new Government was formed with Hr. J. E. Sunila as premier. It is the first purely Agrarian Government in Finland. In Sept. 1927 Finland was elected to the Council of the League of Nations.

Music.—Music in Finland has been, despite the country's store of earlier folk-song, a plant of somewhat recent growth, dating back indeed not much earlier than about the middle of the 19th century. Since then, however, Finland has produced a number of composers of genuine worth, headed by Jan Sibelius (*q.v.*) who has taken his place by general consent among the foremost masters of his time. Whether in his sombre and intensely individual symphonies, in his beautiful songs or in his more popular occasional works, such as "En Saga" and "Finlandia," Sibelius, who has enjoyed a life grant from the State since 1897, has indeed long since established his claims as a national composer of the first rank and as such has won universal recognition both at home and abroad. Other Finnish composers of outstanding note have been Toivo Kuula (1883–1918) whose career was unhappily cut short by his assassination during the Finnish War of Independence; Erkki Melartin (b. 1875), Oskar Merikanto (1868–1924), Armas Järnefelt (b. 1869) and Selim Palmgren (b. 1878). (X.)

FINLAY, ROBERT BANNATYNE FINLAY, 1st VISCOUNT, (1842–1929), British lawyer and politician, was born at Edinburgh July 11, 1842. He was educated at Edinburgh academy and university, and graduated in medicine. In 1867 he was called to the bar, in 1882 becoming a Q.C. and a bencher of the Middle Temple. From 1885 to 1892 he sat as a Conservative for Inverness Burghs, and in 1895 regained the seat and was made Solicitor-General in Lord Salisbury's Govt., when he was knighted. In 1900 he became Attorney-General, remaining in the Govt. until the Conservative defeat of 1906, and from 1902 to 1903 was lord rector of Edinburgh university. In 1910 he was elected M.P. for Edinburgh and St. Andrews universities, and in 1916, on the formation of Mr. Lloyd George's Govt., became Lord Chancellor and received a barony. He retired in 1918, and in 1919 was created a viscount. In 1920 he was appointed British member of the Permanent Court of Arbitration at The Hague, and in 1921 became a member of the Permanent Court of International Justice. He died March 8, 1929.

FINLAY, GEORGE (1799–1875), British historian, was born of Scottish parents at Faversham, Kent, on Dec. 21, 1799. He studied for the law in Glasgow, and about 1821 went to Göttingen. In 1823 he went to Greece, being interested in the struggle for Greek independence, and spent 14 months studying the country. At Missolonghi he met Byron, and for two months spent nearly every evening discussing Greek affairs with him. After a short visit to Scotland he returned to Greece, where he spent the rest of his life. In 1827 he took part in the unsuccessful operations of Lord Cochrane and Sir Richard Church for the relief of Athens. When independence was secured in 1829 he bought an estate in Attica, and tried, without much success, to

introduce better methods of agriculture in Greece. He then turned to the systematic study of Greek history with which he occupied himself until his death in Athens on Jan. 26, 1875.

The first part of his great work appeared in 1844, under the title of *Greece under the Romans*, and was followed by *History of the Byzantine and Greek Empires from 716-1453* (2 vols., 1854); *History of Greece under the Ottoman and Venetian Domination* (1856) and *History of the Greek Revolution* (2 vols., 1861). From 1864 to 1870 he was correspondent of *The Times*.

BIBLIOGRAPHY.—H. F. Tozer's edition of his *History of Greece from its Conquest by the Romans to the present time, B.C. 146-A.D. 1864* (Oxford, 7 vols. 1877), which includes the books mentioned above, contains also a fragmentary autobiography. Finlay's *Greece under the Romans and History of the Byzantine Empire from 716 to 1077* have been published in the Everyman Edition (1906).

FINNER, the name used by whalers to denote the porpoises (*q.v.*) (see also CETACEA).

FINNISH LITERATURE. The earliest writer in the Finnish vernacular was Michael Agricola (1506-1557), who published an *A B C* book c. 1542, and, as bishop of Åbo, a number of religious and educational works. A version of the New Testament in Finnish was printed by Agricola in 1548, and some books of the Old Testament in 1551-52. A complete Finnish Bible was published at Stockholm in 1642. The dominion of the Swedes was very unfavourable to the development of anything like a Finnish literature, the poets of Finland preferring to write in Swedish and so secure a wider audience. It was not until, in 1835, the national epos of Finland, the *Kalevala* (*q.v.*), was introduced to readers by the exertions of Elias Lönnrot (*q.v.*) that the Finnish language was used for literary composition. During the last quarter of the 19th century there was an increasing literary activity in Finland. A noted contribution to a history of Finnish literature is Krohn's *Suomenkielinen runollisuus ruotsinvalian aikana* (1862). A great work in the revival of an interest in the Finnish language was done by the *Suomalaisen Kirjallisuuden Seura* (the Finnish Literary Society), which from the year 1841 has published a valuable annual, *Suomi*. The Finnish Literary Society has also published a new edition of the works of the father of Finnish history, Henry Gabriel Porthan (d. 1804).

In imaginative literature Finland has produced several important writers of the vernacular. Alexis Stenwall ("Kiwi") (1834-72), the son of a village tailor, was the best poet of his time; he wrote popular dramas and an historical romance, *The Seven Brothers* (1870). Among recent playwrights Minna Canth (1844-97) has been the most successful. Other dramatists are P. Cajander (1846-1913), who translated Shakespeare into Finnish, and Karl Bergbom (1843-1906), the first manager of the Finnish national theatre. Among lyric poets is J. H. Erkkö (1849-1906). The earliest novelist of Finland, Pietari Päiväranta (1827-1913), was the son of a labourer; he is the author of a grimly realistic story, *His Life*. Many of the popular Finnish authors of our day are peasants. The most gifted of the writers of Finland, however, is certainly Juhani Aho (1861-1921), the son of a country clergyman. His earliest writings were studies of modern life, very realistically treated. Aho then went to reside in France, where he made a close study of the methods of the leading French novelists of the newer school. About the year 1893 he began to publish short stories, some of which, such as *Ennis*, *The Fortress of Matthias*, *The Old Man of Korpela* and *Finland's Flag*, are delicate works of art, while they reveal to a very interesting degree the temper and ambitions of the contemporary Finnish population. It has been well said that in the writings of Juhani Aho can be traced all the idiosyncrasies which have formed the curious and pathetic history of Finland in recent years.

The most notable of the younger prose writers are Johannes Linnankoski (1869-1913) and F. E. Sillanpää (b. 1888). Linnankoski achieved European renown by his novel *Laulu tulipunaaisesta kukasta* (1905)—"The Song of the Blood-Red Flower"—which has been translated into a number of languages. His best work from an artistic point of view is *Pakolaiset* (1908). Sillanpää has written several collections of short stories dealing with peasant life, and one great novel dealing with the time of the Red insurrection, which is an important document of social history. His

strength lies in psychological descriptions of subconscious states. No other Finnish writer has been so successful in depicting the atmosphere in which the peasant lives his everyday life.

Of the numerous women writers, the following deserve mention: Aino Kallas (b. 1878), short-story writer; two of her volumes being published in English in 1924 and in 1927. The wife of an Estonian scientist and diplomat, she obtained an intimate knowledge of Estonian life, which forms the subject of many of her stories. Mailo Talvio (b. 1871) has written numerous novels concerning life among the peasants and higher ranks of society. Maria Jotuni (b. 1880) possesses a realistic power and a robust humour which inform all her stories, novels and comedies. L. Onerva (b. 1882) is best known for her lyric poetry, but has also written fiction and plays.

Among the poets writing in Finnish, Eino Leino (1878-1925) was unusually productive. He published dramas in prose and verse, novels, short stories, literary studies and numerous volumes of lyric poetry. His most successful works are his *Helkavirsiä*, historic poems in ballad form of a strongly national colour. Leino has also translated Dante's *Divine Comedy* into Finnish blank verse. Larin Kyösti (b. 1873) is another prolific writer who has achieved a well-deserved popularity by his popular poetry. The lyric poetry of Otto Manninen (b. 1872) is highly esteemed by connoisseurs. Manninen did invaluable work as translator of the *Iliad*, the *Odyssey*, Molière's metric comedies and other works. V. A. Koskenniemi (b. 1885), professor of literature at the Finnish University of Turku (Åbo), has published numerous volumes of poetry.

Literature in Swedish.—The Swedish literature of Finland includes a number of poets who have gained reputations both in their own country and in Scandinavia. The greatest poet of Finland was Johan Ludvig Runeberg (*q.v.*; 1804-77), whose reputation rivals that of Tegnér. The most popular author at the close of the 19th century was Zachris Topelius (b. 1818; d. 1898). Mikael Lybeck (1864-1925) achieved his first successes with lyric poetry, but abandoned verse for prose during the last 20 years of his life. Bertel Gripenberg (b. 1878) is the chief master of form among the poets writing in Swedish. The characteristics of his first volumes were dark passion, sensualism, pessimism and an aristocratic romanticism, but he has also found words to sing of the Finnish wildernesses, and has written patriotic lyrics, inspired by the Red insurrection and the war of independence, in which an echo of Runeberg's heroism may be heard. Jacob Tegen-gren (b. 1875) writes in an elegiac key, and descriptions of nature occupy a large part of his works. Hjalmar Procopé (b. 1868) is best known as a lyric poet. Arvid Mörne (b. 1878) sings of the archipelago, peasant life and the scenery of the Swedish-speaking districts in the south of Finland. But Mörne's writings also reflect his deep, radical opinions. He was ardently interested in social reform and the movement for popular education. Mörne also achieved success as a dramatist and novelist.

Emil Zilliacus (b. 1878) published some highly appreciated collections of lyric poetry. Jarl Hemmer (b. 1893) is the most lyrical and spontaneous of the Swedish poets of Finland. His poetry still preserves something of the melodiousness characteristic of Topelius's lyrics. Hemmer's verse has a winning, youthful charm, which yet does not preclude the expression of loftiness of thought. He also wrote a play, short stories and a novel dealing with the time of the war of independence.

Runar Schildt (1888-1925) was the most eminent writer of Swedish prose in Finland. His short stories are characterized by a highly developed style, penetrating psychological insight and a humane, tolerant view of life. The subjects of some of them were taken from the war of independence and the Red insurrection. Schildt was also a very successful dramatist. Vers libre and expressionist prose also found enthusiastic and, in some cases, gifted champions among the writers of Finland both in Swedish and Finnish.

land, Land, folk, rike* (1923-25). (Y. H.)

FINN MAC CUMHAILL (fin mā-kōōl') was probably the
general to whom Cormac mac Airt, king in Tara (fl. c. A.D. 250)
entrusted the task of organizing a standing army, whereby he
sought to establish a suzerainty over the whole of Ireland. But
he has attracted to himself a vast body of popular legend, and
has thus become a mythological figure which dominates the folk-
lore of the Gaelic peoples, in Ireland, Scotland and the Isle of
Man. It is difficult to trace the growth of the legend, owing to a
paucity of early materials. The tales told of the hero were of a
popular nature, transmitted by word of mouth, and did not assume
a literary form so soon as the mythologies of the Tuatha Dé
Danann or the sagas of Cú Chulainn. In these tales Finn is
represented as being the leader of a band of braves, of strongly
contrasted characters—which the story-tellers generally manage
to preserve with remarkable consistency and with no little humour.
They wander about with a seeming lack of aim, but they are
employed in defending Ireland against foreign invaders (as in
the well-known tale of the *Battle of Ventry*), and in the intervals
devote themselves to the pleasures of the chase. They are not
always united; they belong to opposing families; and the best-
known tale of the cycle is that of Finn's pursuit and destruction
of his lieutenant Diarmait, who had eloped with his destined bride,
Gráinne, daughter of Cormac mac Airt.

The best collection of material for studying the growth of the
Finn legend will be found in Kuno Meyer's *Fianaigecht* (Royal Irish
Academy, 1910). Specimens of tales about Finn will be found in
every collection of Irish or Scottish Gaelic folklore. (R. A. S. M.)

FINNO-UGRIAN, the designation of a division of the Ural-
Altaic family of languages and their speakers. The term Finn
is the name given by their neighbours, though not used by them-
selves, to the inhabitants of the eastern shores of the Baltic. It
is probably the same word as the Fenni of Tacitus and *Φίννοι*
of Ptolemy, though it is not certain that those races were Finns
in the modern sense. It possibly means people of the fens or
marshes, and corresponds to the native word *Suomi*, which ap-
pears to be derived from *suo*, a marsh. Finn and Finnish are
used of the inhabitants of Finland and of similar tribes found in
Russia and sometimes called Baltic Finns and Volga Finns. In
this sense the Estonian tribes (Baltic), the Lapps, the Cheremiss
and Mordvins (Volga), and the Permian tribes are all Finns.
The Ostiaks, Voguls and Magyars form a separate subdivision
called Ugrian, from Yura or Ugra, the country on either side of
the Ural Mountains.

The name Finno-Ugric is primarily linguistic. The Finno-
Ugrians form, with the striking exception of the Hungarians, a
moderately homogeneous whole. They are nomads, but are
hardly ever warlike and have no power of political organization.
Those of them who have not come under European influence live
under the simplest form of patriarchal government.

In Russia the Finno-Ugric tribes are widely spread in the
wooded country, especially on the banks of lakes and rivers. They
form a considerable element in the population of the northern,
middle and eastern provinces of Russia, but are not found much
to the south of Moscow (except in the east) or in the west (except
in the Baltic provinces). The Finno-Ugric (or Palaeo-Arctic)
people have black or even reddish hair, sparse beards, yellowish
to whitish skin, short stature, flat heads, flat faces, high cheek
bones, oblique eyes and straight or concave noses. The head
index varies from long to round.

The following are the principal Finnish peoples. The *Permians*
and *Syryenians* (Syryenian, Sirianian, Zyrjenian, Zirian) may be
treated as one tribe. They both call themselves Komi and speak
a mutually intelligible language, allied to Votiak. The name
Bjarmisch is sometimes applied to this sub-group. Both Per-
mians and Syryenians are found chiefly in the governments of
Perm, Vologda and Archangel. The Syryenian headquarters are
at the town of Ishma on the Pechora, whereas the name Permian

is more correctly restricted to the inhabitants of the right bank
of the upper Kama. The *Votiaks* dwell chiefly in the south-eastern
part of the government of Viatka. They call themselves Ud-murt
or Urt-murt. The Cheremiss, who call themselves Mari, inhabit
the banks of the Volga, chiefly in the neighbourhood of Kazan.

The *Mordvinians*, also called Mordvá, Mordvins and Mordvys,
are scattered over the provinces near the middle Volga, especially
Nizhni Novgorod, Kazan, Penza, Tambov, Simbirsk, Ufa and
even Orenburg. Though not continuous, their settlements are con-
siderable both in extent and population. They are the most im-
portant of the Eastern Finns, and their traditions speak of a
capital and of a king who fought with the Tatars. They are men-
tioned as Mordens as early as the 6th century, but now call them-
selves after one of their two divisions, Moksha or Erza. Their
language (two dialects) is derived from Early Finnish, and has
constructions peculiar to itself.

The *Lapps* are found in Norway, Sweden and Finland. They
call themselves Sabme, but are called Finns by the Norwegians.
They are the shortest and most roundheaded race in Europe. The
majority are nomads who live by pasturing reindeer, and are
known as Mountain Lapps, but others have become more or less
settled and live by hunting or fishing. From ancient times the
Lapps have had a great reputation among the Finns and other
neighbouring nations for skill in sorcery.

The *Estonians* are the peasantry of the former Russian province
Estonia and the neighbouring districts. They have reddish flaxen
hair with a tall element. They are practically a branch of the
Finns, and are hardly separable from the other Finnish tribes
inhabiting the Baltic provinces. They call themselves Mā mēs,
or country people, and their land Rahwama or Wiroma (cf. Fin-
nish, Virolaiset, Estonians).

Livs, Livlanders or Livonians is the name given to the old
Finnish-speaking population of west Livland or Livonia and
north Kurland. They were a warlike and predatory pagan tribe
in the middle ages, and it is possible that they were a mixed
Letto-Finnish race from the beginning. They have become almost
completely absorbed by Letts, and their language is only spoken
in a few places on the coast of Kurland, if indeed it still exists.
It is known as Livish or Livonian and is allied to Estonian.
The *Votes* (to be distinguished from the Votiaks), are also called
southern Chudes and Vatjalaiset. They now occupy only a few
parishes in north-west Ingria. The *Vepsas* or *Vepses*, also called
Northern Chudes, another tribe allied to the Estonians, are found
in the district of Tikhvinsk and other parts of the former govern-
ment of Old Novgorod.

The *Finns* proper or Suomi, as they call themselves, inhabit
Finland and the Olonetz, Tver and governments of Leningrad.
Formerly a tribe of them called Kainulaiset was also found in
Sweden, whence the Swedes call the Finns Qven. At present
there are two principal subdivisions of Finns, the Tavastlanders
or Hämäläiset in the south and west and the Karelians or Kar-
jalaiset in the east and north. The Tavastlander has a round head,
a broad face, concave nose, fair complexion, frequently light hair
and blue or grey eyes. The Karelians have broader heads and are
shorter.

CIVILIZATION AND RELIGION

Finno-Ugric tribes have not progressed so much. The Finns and
Magyars, have adopted, at least in towns, the civilization of
Europe; others are agriculturists; others still nomadic. The
wilder tribes, such as the Ostiaks, Voguls and Lapps, mostly con-
sist of one section which is nomadic and another which is settling
down. Traces of ancient conditions survive sporadically but are
nowhere universal. Few except the Hungarians have shown them-
selves warlike. But most Finno-Ugrians are astute and persevering
hunters, and the Ostiaks still shoot game with a bow. The tribes
are divided into numerous small exogamous clans and are gen-
erally patrilineal. Marriage by purchase of the bride is the more
general form. Women are often excluded from religious cere-
monies. The most primitive form of house consists of poles in-
clined towards one another and covered with skins or sods, so
as to form a circular screen round a fire; winter houses are partly
underground. Long snow-shoes are used in winter and boats are

largely employed in summer. The Finns in particular are very good seamen. The Ostiaks and Samoyedes still cast tin ornaments in wooden moulds. The deities are chiefly nature spirits and the importance of the several gods varies as the tribes are hunters, fishermen, etc. Sun or sky worship is found among the Samoyedes and *Jumala*, the Finnish word for god, seems originally to mean sky. The Ostiaks worship a water-spirit of the river Obi and also a thunder-god. We hear of a forest-god among the Finns, Lapps and Cheremiss. There are also clan gods worshipped by each clan with special ceremonies. Traces of ancestor-worship are also found. The Samoyedes and Ostiaks are said to sacrifice to ghosts, and the Ostiaks to make images of the more important dead, which are tended and honoured, as if alive, for some years. Images are found in the tombs and barrows of most tribes, and the Samoyedes, Ostiaks and Voguls still use idols, generally of wood. Animal sacrifices are offered, and the lips of the idol sometimes smeared with blood. Quaint combinations of Christianity and paganism occur; thus the Cheremiss are said to sacrifice to the Virgin Mary. The idea that disease is due to possession by an evil spirit, and can be both caused and cured by spells, seems to prevail among all tribes, and in general extraordinary power is supposed to reside in incantations and magical formulae. Almost every tribe has its own collection of prayers, healing charms and spells to be used on the most varied occasions. A knowledge of these formulae is possessed by wizards (Finnish *noita*) corresponding to the Shamans of the Altaic peoples. They are exorcists and also mediums who can ascertain the will of the gods; a magic drum plays a great part in their invocations, and their office is generally hereditary. The non-Buddhist elements of Chinese and Japanese religion present the same features as are found among the Finno-Ugrians—nature-worship, ancestor-worship and exorcism—but in a much more elaborate and developed form.

History.—Most of the Finno-Ugrian tribes have no history or written records, and little in the way of traditions of their past. In their later period the Hungarians and Finns enter the course of ordinary European history. For the earlier period we have no positive information, but from archaeological and philological data an account of the ancient wanderings of these tribes may be constructed. Barrows containing skulls and ornaments may mark the advance of a special form of culture. But clearly all such deductions contain a large element of theory, and the following hypothesis has been proposed by Peake. (*J.R.A.I.* xlix. 1919.) In late Palaeolithic times various types of long-headed men occupied the plain of N. Europe. Then came in Solutrian times a nomadic people from Eurasia, hunters of wild horses. Then a broadheaded race of perhaps Mongol affinities pressed to the Baltic. The Nordic Steppe folk spread north and about the middle of the Bronze age came into touch with the Mongoloids who were reinforced by later waves. "Thor must have led his red-haired followers from the banks of the Volga, while Woden brought his fair-haired warriors from the Russian Steppes."

BIBLIOGRAPHY.—Harold Peake, "The Finnic Question," *J.R.A.I.* xlix. (1919). See A. C. Haddon, *Races of Man* (1924); R. B. Dixon, *Racial History of Man* (1923); H. J. Fleure, *The Peoples of Europe* (1922).

FINNO-UGRIAN LANGUAGES. This family of languages comprises (1) The *Lapp* language, spoken by about 30,000 reindeer nomads, fishermen and peasants in the northern parts of Norway, Sweden and Finland and on the Kola peninsula in Russia with numerous dialects and several written languages of which the chief is Norwegian Lappish. (2) *Baltic-Finnish languages*: (a) the *Finnish* language spoken in Finland, except certain districts in the south and west and on the Åland isles where Swedish is spoken, in certain parts of north Sweden, Norway and Russia near the Finnish boundary, as well as in U.S.A.; in all by more than 3,000,000 persons. Since the middle of the 19th century Finnish has developed into a modern culture-language with a comprehensive literature. The Finnish dialects in east Finland are connected with (b) the *Karel* or Russian-Karel language, nearly allied to which is (c) *Olonez*, spoken on both sides of the boundary north of Ladoga, east of which are (d) the *Lydi* dialects, forming on their side the transition to (e) the *Veps* lan-

guage on the western edge of Lake Onega and in some smaller groups of villages farther to the south; (f) *Vot*, an expiring idiom in the north-western part of Ingermanland, spoken by about 1,000 peasants; (g) *Estonian*, used by about 1,000,000 people in the republic of Estonia and by about 400,000 in colonies in Russia, Siberia and Lettland. During the last two decades this language has developed energetically towards a modern culture-language and has a fairly comprehensive literature. The south-east or Dorpat dialect was used earlier as a written language, but at present only the north-west (Reval) dialect is in use. (h) *Liv*, spoken by about 3,000 fishermen and peasants on the north promontory of Courland; formerly spoken round the whole coast of Livonia and Courland. (3) *Mordvin*, with two dialect groups, *Moksha* and *Erza*, spoken by about 1,000,000 peasants in a large number of language-islands on both sides of the Volga, south of its bend. (4) *Cheremiss*, spoken by about 375,000 peasants, on both sides of the Volga and in the south part of Ural. (5) The Permian languages: (a) *Votiak* is spoken by about 425,000 peasants, between the rivers Kama and Vjatka; (b) *Zyrian* is spoken by about 250,000 people, scattered along the rivers Vychegda, Mezen, Pechora and Kama, and on the peninsula of Kola and in the south called Permiaks. Owing to the Russian revolution the Mordvins, Cheremiss, Votiaks and Zyrians obtained the right to use their own languages in schools and press, so that a large number of books and newspapers printed in these idioms now appear. (6) The *Ob-Ugrian* languages: (a) *Vogul* is spoken by about 5,000 peasants, hunters and reindeer breeders, scattered over an extensive tract on both sides of the central Ural; (b) the allied *Ostiak* language is used by about 20,000 fishermen, hunters and, in the north, reindeer nomads, along the middle and lower courses of Ob and Irtysh and their tributaries. (7) *Hungarian* (*q.v.*). The Ob-Ugrian languages and the Hungarian taken together form the Ugrian group of languages, from a tribe *Ugra* mentioned in ancient Russian chronicles.

The Finno-Ugrian languages are distantly related to the *Samoyed* languages and with them form the *Uralian* family of languages. It is said that this family is related to the *Altaic* family of languages, consisting of the *Turko-Tataric*, *Mongolian* and *Manchu-Tungus* languages and according to some scholars the *Japanese* language, under the term the *Uralo-Altaic* family of languages. No valid reasons for this classification have yet been produced. The term "Turanian" is equally devoid of value. It is possible that the Finno-Ugrian languages are distantly related to Indo-European; this question, however, is far from being finally solved. In any case Hungarian and Finnish, etc., are not Slavonic languages but independent, with their own structure and their own vocabulary. From time immemorial, however, they have adopted large numbers of loanwords from the adjacent Indo-European idioms, evidence of the early contacts between the Finno-Ugrians and their more civilized neighbours, which is of the greatest value for the historical investigation of these languages. The Iranian loanwords are the oldest of them all. Lithuanian words in Finnish were partly adopted during the bronze age. The oldest Germanic loanwords in Finnish and Lapp date from before the Viking age and the Slavonic loanwords in Hungarian and Finnish and the Turko-Tataric words in Hungarian and other eastern Finno-Ugrian languages came in historic conditions.

Finnish and Hungarian, though related, are about as widely separated from each other as English and Persian. Finnish stands in about the same relationship to the Estonian and Liv languages as German does to the Scandinavian languages. The linguistic relationship between the peoples who speak these languages does not always signify that the peoples themselves are racially related. From an early period the Finno-Ugrian languages seem to have been associated with an east European race, often called the East Baltic which probably is preserved in its purest form among the Finns. The Lapps, however, who belong to quite another, primitive and isolated race, adopted their present language from some Finnish group long before the birth of Christ, and this, too, was perhaps the case with the Ob-Ugrian speakers.

The Finno-Ugrian languages are in an eminent degree suffixing languages and construct their grammatical forms by the addition

of a great number of endings. The declension includes many cases, e.g., in Finnish about fifteen. Gender is not marked. Some languages possess a dual form as well as plural. The verbs are abundantly developed, and in some languages subjective and objective conjugation are sharply distinguished. Instead of negative adverbs most languages have a negative conjugation. The grammar shows many complicated phonetic alternatives, e.g., the intricate alternation of "strong" and "weak" stem consonants in Lapp and Finnish and the laws of vocalic harmonization in many languages. In the Finno-Ugrian languages, which still retain their original syntax, the sentence structure has many infinitive and participial constructions.

FINSBURY, a metropolitan borough of London, England, bounded north by Islington, east by Shoreditch, south by the City of London, and west by Holborn and St. Pancras. Pop. (1901) 101,463; (1931) 69,888; area 587 ac., being the smallest borough in London except Holborn. The main outlines of the borough are Pentonville road on the north, from King's cross to the Angel, Islington; thence south along the City road to the confines of the City at Finsbury pavement in Moorgate; from here westward to Farringdon street; and thence north along Farringdon and King's Cross roads. "The 'Angel,' at Islington," once a famous 17th century coaching inn, lies within the borough; and from here Goswell road, the residence of Dickens's *Pickwick* (continued as Aldersgate street), St. John street, and Rosebery avenue radiate through the borough. Clerkenwell road and Old street cross it from west to east. The old distinctions of Clerkenwell on the west and Finsbury on the east of the borough are still commonly used. The commercial character of the City extends into the borough, accounting for the decline of its resident population. Local industries include tobacco manufacture, printing, and the optical glass and jewellery trades. Owing to the proximity of the City markets, it is an important centre of the transport trade. The large modern parcels dépôt of the General Post Office is at Mount Pleasant in Rosebery avenue; close by are the head offices of the Metropolitan Water Board, with the former reservoirs of the New River Head, and the Finsbury town hall. Watch-making, once a leading industry, has declined, but is still represented by the British Horological Institute situated in the borough.

Finsbury is supposed to take its name from the extensive marshland or "fens," anciently known as Vynesbury Moor and Moorfields, which lay outside the city walls at Moorgate. This was drained in the 16th century, and subsequently laid out as public grounds. Chalybeate springs were discovered here at the end of the following century, so that it became a popular resort and even a spa, as the names of Spa Fields and Sadler's and other wells commemorate. Pepys mentions its houses of entertainment and that it furnished a refuge for many whose houses were destroyed in the fire of London. Bookstalls and other booths were numerous at a somewhat later date.

The borough includes several memorials of historical interest. In the old parish of Clerkenwell (*q.v.*) is the former priory of the Order of St. John of Jerusalem, the English headquarters of the Order. West of Aldersgate street stand the buildings of the Charterhouse (*q.v.*), originally a Carthusian monastery, subsequently a hospital and a school, out of which grew the great public school, removed to Godalming in 1872. Bunhill fields, City road, is the famous burial-ground used by the Dissenters from the middle of the 17th century until 1852. Among eminent persons interred here are John Bunyan, Daniel Defoe, Susanna, mother of John and Charles Wesley, and William Blake, the poet and engraver. George Fox, founder of the Society of Friends, is buried close by in the grounds attached to the Memorial buildings of the society. Facing Bunhill fields is the chapel associated with the Wesleys, and the house of John Wesley, opened as a museum bearing his name. In Bunhill row John Milton died. South of the fields lies the Artillery ground (6 ac.) of the Honour-

able Artillery Company, so occupied since 1641, with barracks and an armoury house (1735). Sadler's Wells theatre, Rosebery avenue, preserves the name of the fashionable medicinal spring, music room and theatre opened in 1683 by Thomas Sadler. In 1765 a new theatre was built, notable in its connection with the names of Joseph Grimaldi the clown (d. 1837) his father the ballet master, and others, and the era of Shakespeare representations under Samuel Phelps (1844-62). The theatre walls still stand and public efforts were being made (1928) to restore its traditions.

Among the educational institutions are Merchant Taylors' school, founded in 1561, and removed here from the City in 1875 to new buildings on the former site of Charterhouse school; the Northampton Polytechnic institute (1898); and the Dame Alice Owen secondary schools for boys and girls founded in 1612 and supported by the Brewers' company. St. Luke's printing works in Old street, erected in 1751 as a hospital, are now the Bank of England printing works. The Smithfield Martyrs' Memorial church (1871) is in St. John street. Other institutions are St. Mark's, the City of London Maternity and the Royal London Ophthalmic hospitals. The metropolitan borough of Finsbury was formed in 1900 out of the vestries of Clerkenwell, the Charterhouse and other parishes. By the Representation of the People Act, 1918, its parliamentary representation was reduced from two members to one member. As a county division it returns two members to the London County Council. The acreage of its open space (11 ac. including Bunhill fields) is one of the smallest of any of the London boroughs. The borough council consists of a mayor, nine aldermen and 56 councillors.

FINSSEN, NIELS RYBERG (1860-1904), Danish physician and originator of the Finsen lamp for treatment of skin diseases, was born on Dec. 15, 1860, at Thorshavn, in the Faeroe islands. His parents were Icelandic, and the boy spent his early years at school in Reykjavik. The contrasts in the light and darkness of the north interested him very early, and the discovery that he worked better in a well-lighted room started him on a study of the effect of light on physical organisms. He graduated from the University of Copenhagen in 1890 as a doctor of medicine, and was prosecutor there for three years. He resigned to conduct experiments on the physiologic effect of light, and in 1893 published a paper on the treatment of smallpox by red light to exclude the actinic (blue, violet and ultra-violet) rays of ordinary light and thus prevent suppuration of the lesions with subsequent scar formation. Later he found that the actinic rays of sunlight, which were detrimental to smallpox, were responsible for the bactericidal property of sunlight. This knowledge enabled him to develop the effective treatment of *lupus vulgaris* by ultra-violet rays.

The publication in 1896 of Finsen's best known work "on the employment in medicine of concentrated chemical light rays" brought him immediate fame and a small pension from the Government, on which he lived while he continued his experiments. In 1895 he published his general theory of the effect of light on living organisms; *i.e.*, that it is the actinic rays found in the blues and violets of the spectrum which possess curative value and stimulating influence, and not, as had been hitherto supposed, the physical action of light and heat. After practical tests for two years, he published *The Treatment of Lupus Vulgaris by Concentrated Chemical Rays* (1897).

Through the generosity of two wealthy Danes, G. A. Hagemann and Vilh. Jørgensen, and with a Government loan, his Light institute was founded in Copenhagen in April 1896. It had a capacity for treating 200 patients daily, and equipment for making and supporting scientific research concerning the action of light upon living organisms, with the purpose of applying the results to the service of practical medicine. In 1910 98% cures had been accomplished in the treatment of 2,000 patients. Finsen was awarded the Nobel prize of 100,000 crowns in 1903, half of which he gave to the institute, and arranged that the other half should revert to it on the death of his heirs. From the age of 23 Finsen was practically an invalid. For the last few years of his life, he had to direct the work of the institute from his home in Copenhagen.

He died on Sept. 24, 1904.

See *Canadian Institute Transactions*, vol. viii., pp. 99-135 (Toronto, 1905); Cleveland Moffett, "Finsen and the Story of His Achievement," *McClure's Magazine* (Feb. 1903); and *Nature*, vol. lxx., p. 532. (A. U. D.)

FINSTERWALDE, a town of Germany, in the Prussian province of Brandenburg, on the Schackebach, a tributary of the Little Elster, 28 m. W.S.W. of Cottbus by rail. Pop. (1925) 13,434. The town, which is first mentioned in 1288, came into the possession of electoral Saxony in 1635 and of Prussia in 1815. It has a Gothic church (1581), a château, cloth, rubber and cigar factories, saw mills and factories for machine building.

FIORINZO DI LORENZO (c. 1445-1525), Italian painter of the Umbrian school, born at Perugia, where he was a member of the gild of painters, and in 1472 was elected decemvir of the city. On Dec. 9 of the same year he was commissioned to paint an altarpiece for Santa Maria Nuova; this work has been identified with a pentatych representing the "Madonna and Saints," now in the Pinacoteca of Perugia. It resembles in style Fiorenzo's only signed picture, dated 1487, which is also at the Pinacoteca, having been removed from S. Francesco al Prato. It represents St. Peter and St. Paul standing on either side of a niche, with the "Virgin and Angels" in the lunette. These are the only two authenticated pictures of the master extant. Recent art criticism has ascribed to him without sufficient reason some fifty pictures, differing widely in style; of these only about a dozen can with any degree of certainty be given to him on stylistic evidence. Most of them are in the Pinacoteca of Perugia; very few can be found outside his native city. The Stædal Institute at Frankfurt possesses a fine "Madonna with Saints"; the London National Gallery portions of a polyptych representing the "Madonna with Saints and Angels." In comparison with the work of his Umbrian predecessors, Fiorenzo's style displays a marked advance in the definition of form. His drawing is vigorous and sure. His rendering of drapery, with sinuous sharply defined folds, and of landscape with finely constructed river scenes and towns, recalls the art of Benozzo Gozzoli. It seems probable, therefore, that Fiorenzo derived his training indirectly from this great Florentine. He may have worked under Niccolò da Foligno, whose picture, dated 1458, at Deruta, the National Gallery Fiorenzo closely resembles both in style and arrangement. Following on the primitive art of Umbria it was one of Fiorenzo's merits to have introduced the ideas of the Florentine Renaissance to Perugia, and thereby to have prepared the way for the great age of Perugino and Pintoricchio. Soon after 1475 Pintoricchio probably worked as an assistant in Fiorenzo's workshop; and to the co-operation of master and pupil may be ascribed the fine "Adoration of the Magi" in the Pinacoteca.

FIORILLO, JOHANN DOMINICUS (1748-1821), German painter and historian of art, was born at Hamburg on Oct. 13, 1748. In 1784 he became keeper of the collection of prints at the university library at Göttingen. He was appointed professor extraordinary in the philosophical faculty in 1799, and ordinary professor in 1813. He died at Göttingen on Sept. 10, 1821. His works include *Geschichte der zeichnenden Künste* (5 vols., 1798-1808), and *Geschichte der zeichnenden Künste in Deutschland und den Vereinigten Niederlanden* (4 vols., 1815-20).

FIR, the Scandinavian name originally given to the Scotch pine (*Pinus sylvestris*) and now sometimes employed as a general term for the whole of the true conifers (Abietoideae), but in a more exact sense, it has been transferred to the "silver firs," the genus *Abies* of modern botanists. (See GYMNOSPERMS.)

The firs are distinguished from the pines and larches by having their needle-like leaves placed singly on the shoots, instead of growing in clusters from a sheath on a dwarf branch. Their cones are composed of thin, rounded, closely imbricated scales, each with a more or less conspicuous bract springing from the base. The trees have usually a straight trunk, and a tendency to a

conical or pyramidal growth, throwing out each year a more or less regular whorl of branches from the foot of the leading shoot, while the buds of the lateral boughs extend horizontally. The cones are erect, and their scales drop off when the seed ripens; the leaves spread in distinct rows on each side of the shoot.

There are about 25 species of the true fir (*Abies*), widely distributed in the Northern Hemisphere. The silver fir (*A. pectinata*), a representative Old

BY COURTESY OF "AMERICAN FORESTS AND FOREST LIFE MAGAZINE"

DOUGLAS FIRS IN VIRGIN FORESTS OF NORTHWESTERN UNITED STATES

World species, is a lofty tree, sometimes 150 ft. high, with large spreading horizontal boughs curving upward toward the extremities. The flat leaves are arranged in two regular distinct rows; they are deep green above, but beneath have two broad white lines, which, as the foliage in large trees has a tendency to curl upwards, give it a silvery appearance from below. The large cones stand erect on the branches, are cylindrical in shape, and have long bracts, the curved points of which project beyond the scales. When the tree is young the bark is of a silvery grey, but gets rough with age. It is abundant in most of the mountain ranges of southern and central Europe, but is not found in the northern parts of that continent. In Asia it occurs on the Caucasus and Ural, and in some parts of the Altaic chain. Extensive woods of this fir exist on the southern Alps, where the tree grows up to nearly 4,000 ft.; in the Rhine countries it forms a great part of the extensive forest of the Hochwald and occurs in the Black Forest and in the Vosges; it is plentiful likewise on the Pyrenees and Apennines. The wood is inferior, but, being soft and easily worked, is largely employed in the countries to which it is indigenous for all the purposes of carpentry. Deficient in resin, the wood is more perishable than that of the spruce when exposed to the air, though it is said to stand well under water. The bark contains a large amount of a fine, highly resinous turpentine, which collects in tumours on the trunk during the heat of summer. After purification by straining, it is sold as "Strasbourg turpentine," much used in the preparation of some of the finer varnishes. Burgundy pitch is also prepared from it by a similar process as that from the Norway spruce. A fine oil of turpentine is distilled from the crude material; the residue forms a coarse resin. Introduced into Great Britain at the beginning of the 17th century, the silver fir has become common there as a planted tree, though, like the Norway spruce, it rarely comes up from seed scattered naturally; it is also planted as an ornamental tree in eastern North America.

Several other Old World firs are successfully grown for ornamental purposes in Europe and North America. Among these are the Spanish fir (*A. Pinsapo*); the Greek fir (*A. cephalonica*); the Algerian fir (*A. numidica*); the Cilician fir (*A. cilicica*), of Asia Minor; the Nordmann fir (*A. Nordmanniana*), of the Caucasus; and the Momi fir (*A. firma*), the Nikko fir (*A. homolepis*) and the Veitch fir (*A. Veitchii*), of Japan.

In North America there are ten native species of fir, found chiefly from the Rocky Mountains westward and attaining their maximum development in the Sierra Nevada and Cascade ranges. Of the two firs occurring in the Eastern States and Canada, the best known is the balsam fir (*A. balsamea*), which is found from Newfoundland to Virginia and northward to Labrador and the Yukon. It is a widely branching tree, 40 ft. to 60 ft. high, with fragrant resinous leaves; it is extensively used for pulp-wood, sparingly for lumber and yields the valuable oleoresin known as Canada balsam (*q.v.*). The smaller southern balsam fir or she-balsam (*A. Fraseri*) is confined to the southern Appalachian Mountains. Several firs of the western United States attain immense size. The white fir (*A. concolor*), sometimes 250 ft. high,

with a trunk diameter of 6 ft., ranges from Wyoming to the Sierra Nevada and southward to Mexico. The lowland white fir (*A. grandis*), occasionally 300 ft. high, is a valley species found from Montana west to Vancouver island and south near the coast to central California. The western silver fir (*A. amabilis*), a beautiful tree native to the Cascade and Olympic ranges from Oregon to British Columbia, reaches a height of 250 ft. and a trunk diameter of 4 ft. to 6 feet. The California red fir (*A. magnifica*), often 200 ft. high, is a handsome tree of the northern Sierra Nevada and the southern Cascade mountains. The noble fir (*A. nobilis*), usually 150 ft. to 200 ft. high, but sometimes 250 ft. high, with a trunk 6 ft. to 8 ft. in diameter, forms large forests in Washington, Oregon and northern California. The smaller alpine fir (*A. lasiocarpa*), commonly 80 ft. to 100 ft. high, is found in the Rocky Mountains from New Mexico to Alaska, and westward to Oregon, Washington and British Columbia. With the exception of the noble fir, the wood of most western firs is inferior to that of pine or spruce, but is used to some extent for lumber and pulp-wood. (See DOUGLAS FIR; HEMLOCK; SPRUCE.)

FIRDOUSĪ, Persian poet. Abu 'l Kāsim Mansur (or Hasan), who took the *nom de plume* of Firdousī (Firdausī or Firdusī), author of the epic poem the *Shāhnāma*, or "Book of Kings," a complete history of Persia in nearly 60,000 verses, was born at Shadab, a suburb of Tūs, about the year 329 of the Hegira (A.D. 941), or earlier. Firdousī was profoundly versed in the Arabic language and literature and had also studied deeply the Pahlavi or Old Persian, and was conversant with the ancient historical records which existed in that tongue.

The *Shāhnāma*, of Firdousī (see also PERSIA: Literature) is perhaps the only example of a poem produced by a single author which at once took its place as the national epic of the people. During the reign of Chosroes I. (Anushirvan) the contemporary of Mohammed, and by order of that monarch, an attempt had been made to collect, from various parts of the kingdom, all the popular tales and legends relating to the ancient kings, and the results were deposited in the royal library. During the last years of the Sassanid dynasty the work was resumed, the former collection being revised and greatly added to by the Dihkan Danishwer, assisted by several learned mobeds. His work was entitled the *Khoda'nāma*, which in the old dialect also meant the "Book of Kings." On the Arab invasion this work was in great danger of perishing at the hands of the iconoclastic caliph Omar and his generals, but it was fortunately preserved; and we find it in the 2nd century of the Hegira being paraphrased in Arabic by Abdallah ibn el Mokaffa, a learned Persian who had embraced Islam. Other Guebres occupied themselves privately with the collection of these traditions; and, when a prince of Persian origin, Yakūb ibn Laith, founder of the Saffarid dynasty, succeeded in throwing off his allegiance to the caliphate, he at once set about continuing the work of his illustrious predecessors. His "Book of Kings" was completed in the year 260 of the Hegira, and was freely circulated in Khorasan and Irak. The Samanid princes who succeeded applied themselves zealously to the same work, and Prince Nūh II., who came to the throne in 365 A.H. (A.D. 976), entrusted it to the court poet Dakiki, a Guebre by religion. Dakiki's labours were brought to a sudden stop by his own assassination, and the fall of the Samanian house happened not long after, and their kingdom passed into the hands of the Ghaznevids. Mahmūd ibn Sabuktāgin, the second of the dynasty (998-1030), collected a vast amount of materials for the work, and after having searched in vain for a man of sufficient learning and ability to edit them

faithfully, he at length made choice of Firdousī. The sultan ordered his treasurer, Khojah Hasan Maimandi, to pay to Firdousī a thousand gold pieces for every thousand verses; but the poet preferred to allow the sum to accumulate till the whole was finished, with the object of amassing sufficient capital to construct a dike for his native town of Tūs, which suffered greatly from defective irrigation, a project which had been the chief dream of his childhood. Owing to this resolution, and to the jealousy of Hasan Maimandi, who often refused to advance him sufficient for the necessities of life, Firdousī passed the latter portion of his life in great privation, though enjoying the royal favour and widely extended fame.

At length, after thirty-five years' work, the book was completed (1011), and Firdousī entrusted it to Ayāz, the sultan's favourite, for presentation to him. Mahmud ordered Hasan Maimandi to take the poet as much gold as an elephant could carry, but the jealous treasurer persuaded the monarch that it was too generous a reward, and that an elephant's load of silver would be sufficient. 60,000 silver dirhems were accordingly placed in sacks, and taken to Firdousī by Ayāz at the sultan's command, instead of the 60,000 gold pieces, one for each verse, which had been promised. Firdousī in a rage gave 20 thousand pieces to Ayāz himself, the same amount to the bath-keeper, and paid the rest to a beer seller for a glass of beer (*fouka*), sending word back to the sultan that it was not to gain money that he had taken so much trouble.

He gave a sealed paper to Ayāz, begging him to hand it to the sultan in a leisure moment after 20 days had elapsed, and set off on his travels with no better equipment than his staff and a dervish's cloak. At the expiration of the 20 days Ayāz gave the paper to the sultan, who on opening it found the celebrated satire which is now always prefixed to copies of the *Shāhnāma*, and which is perhaps one of the bitterest and severest pieces of reproach ever penned. Mahmud, in a violent rage, sent after the poet and promised a large reward for his capture, but he was already in comparative safety. Firdousī directed his steps to Mazandaran, and took refuge with Kabus, prince of Jorjan, who at first received with great favour, and promised him his continued protection and patronage; learning, however, the circumstances under which he had left Ghazni, he feared the resentment of so powerful a sovereign as Mahmud, who he knew already coveted his kingdom, and dismissed the poet with a magnificent present. Firdousī next repaired to Baghdad, and found refuge at the court of the caliph. Firdousī composed a poem of 9,000 couplets on the theme borrowed from the Koran of the loves of Joseph and Potiphar's wife—*Yūsuf and Zuleikha* (edited by H. Ethé, Oxford, 1902; complete metrical translation by Schlechta-Wssehrd, Vienna, 1889). This poem, though rare and little known, is still in existence—the Royal Asiatic Society possessing a copy.

Mahmud finally decided not to pursue Firdousī further and to give him full reparation. The change, however, came too late; Firdousī, now a broken and decrepit old man, had in the meanwhile returned to Tūs, and, while wandering through the streets of his native town, heard a child lisping a verse from his own satire in which he taunts Mahmud with his slavish birth:—

Had Mahmud's father been what he is now
A crown of gold had decked this aged brow;
Had Mahmud's mother been of gentle blood,
In heaps of silver knee-deep had I stood.

He was so affected by this proof of universal sympathy with his misfortunes that he went home, fell sick and died. He was buried in a garden, but Abu'l Kasim Jurjani, chief sheikh of Tūs, refused to read the usual prayers over his tomb, alleging that he was an infidel, and had devoted his life to the glorification of fire-worshippers and misbelievers. The next night, however, having dreamt that he beheld Firdousī in paradise dressed in the sacred colour, green, and wearing an emerald crown, he reconsidered his determination; and the poet was henceforth held to be perfectly orthodox. He died in the year 411 of the Hegira (A.D. 1020), aged about eighty, eleven years after the completion of his great work.

The *Shāhnāma* (which only existed in ms. up to the beginning of the 19th century) was published (1831-68) with a French translation in a

magnificent folio edition, at the expense of the French government, by Julius von Mohl. The size and number of the volumes, however, and their great expense, made them difficult of access, and Frau von Mohl published the French translation (1876-78) with her husband's critical notes and introduction in a more convenient and cheaper form. Other editions are by Turner Macan (Calcutta, 1829), J. A. Vullers and S. Landauer (unfinished; Leiden, 1877-83). There is an English abridgment by J. Atkinson (London, 1832; reprinted 1886, 1892); a verse translation by A. G. and E. Warner (1905-15), with an introduction containing an account of Firdousi and the Shāhnāma; the version by A. Rogers (1907) contains the greater part of the work. The episode of Sohrab and Rustam is well known to English readers from Matthew Arnold's poem. The only complete translation is *Il Libro dei Reî*, by I. Pizzi (8 vols., Turin, 1886-88), also the author of a history of Persian poetry.

See also E. G. Browne's *Literary History of Persia*, i., ii. (1902-06); T. Nöldeke, *Das iranische Nationalepos* (Strasbourg, 1896) for a full account of the Shāhnāma, editions, etc.; and H. Ethé, *Neupersische Litteratur* (Strasbourg, 1896).

FIRE is so familiar that it scarcely needs definition. Its extraordinary usefulness and equally extraordinary dangers impress practically every human being from infancy onward. Ordinary fire is the rapid chemical combination of oxygen with the carbon and other elements of organic substances in such a way that heat, flame and light are produced. In a broader sense fire is the process whereby the combination of one chemical element with another, when reduced to a gaseous condition, produces heat and flame.

Among all the discoveries and inventions made by men, only a few, such as speech, writing and agriculture, have borne such momentous fruit as has the discovery of how to make and use the type of combustion commonly known as fire. The use of fire is the basis of practically all forms of modern manufacturing and transportation; it has been a powerful agent in determining the spread and present distribution of mankind and of civilization; it has perhaps been a major, although indirect agent in causing racial differences in mentality. It is the background and basis of our modern industrial life.

Universality of Fire.—Traces of fire appear among the earliest human relics, far back at the beginning of Paleolithic times. During historic times it is doubtful whether any race or tribe has ever been completely without knowledge of fire. Early travellers, to be sure, have brought back tales like that of the missionary Krapf in East Africa. He heard from a slave that a tribe in southern Shoa lived like monkeys in the bamboo jungles and were totally ignorant of fire. That was in the middle of the 19th century, but no competent observer has yet seen such a tribe. In the same way Wilkes of the famous United States Exploring Expedition in the Pacific reported that no sign of places for cooking, nor any appearance of fire was found in Bowditch Island (Fakafo), but Hale, the ethnographer of the same expedition, reports the native word for fire. We now know that these people not only talked about fire, but have a legend as to its origin and could kindle a blaze. Since other reports of fireless people fare in the same way, Sumner and Keller seem justified in saying that "it is certain that over the whole earth no fireless tribe of men has been found. . . . Man is scarcely man till he is in possession of fire."

Original Use of Fire.—Although we have no real knowledge as to the original use of fire or as to man's discovery of the art of kindling a flame, primitive legends, the usages of primitive people and ancient religious ceremonials give some clue to the major facts. One of the most important conclusions derived in this way is that fire was used long before it could be artificially generated. Lippert even goes so far as to argue that the use of fire enabled man's ape-like progenitor to descend from the trees and walk erect because it gave him protection from other animals. Even if this idea is untenable, as it probably is, one of man's earliest discoveries must have been that he could make profitable use of the fires engendered naturally by lightning, falling meteors, the materials ejected from volcanoes, friction developed by avalanches and boulders and other natural occurrences. He probably soon realized the value of a blaze not only for warmth, but for cooking food, warding off wild beasts and driving game out of the jungle. Thus early man presumably cherished fire long before he learned how to make it.

Preservation of Fire.—Even in modern times many tribes have been observed which carefully preserve their fire year after year and suffer serious loss if it is extinguished. The people of the Andaman islands, who are said to be ignorant of the art of producing fire, take a smouldering stick with them and keep it burning if they go away from their huts for more than a few hours on a hunting or fishing expedition. Among certain Papuans who have

FROM FARABEE, "THE CENTRAL ARAWAKS"
WAPISIANA BOYS OF SOUTHERN
BRITISH GUIANA MAKING A FIRE
The device employed is that of rotating a stick in a round hole in the piece of wood lying on the ground

no means of kindling a blaze, live coals of a very slow-burning wood are constantly preserved in the huts. If by chance the fire goes out, these coast dwellers have to go to the mountains where the inhabitants understand the art of fire-making, and bring thence some live coals. Even where the art of kindling a fire is understood, the technique is often so crude or the difficulties because of damp weather are so great that the fire is preserved with extraordinary care. The Australian aborigines prefer to make long journeys to get fire from another tribe rather than undertake the labour of making it themselves. Among the Herero, to cite one of the many examples given by Sumner and Keller, the difficulty of making fire by friction was formerly so great that the daughters of the household were regularly charged with the care of the flame. If the fire went out, it was regarded as an evil omen.

Fire and Religious Rites.—A great number of facts of this kind agree with some of the most widespread and primitive legends and religious practices. According to the familiar Greek legend, Prometheus brought fire to earth. Sometimes he is said to have lighted a torch at the sun's chariot, and sometimes to have gone underground. In the Cook islands near New Zealand, the Polynesian hero Maui is said to have obtained fire for man by going down to hell where he learned to generate a spark by rubbing two pieces of wood together. Perhaps the multitudinous legends of this sort are reminiscent of the period when the art of making fire was unknown. In such circumstances there must have been repeated periods when prolonged rainy spells or other accidents put out all the fires among the very scanty population of a large area. In such a case no fire may have been available for many years, and the bringer of new fire would be a hero. Perhaps a late relic of the periodic loss of fire is found in certain ceremonies of both the Roman Catholic and Greek Orthodox churches. According to the traditional method, all the lights in the churches are gradually extinguished during Passion Week. When the last light has been extinguished, "new fire" is made; formerly this was done by some primitive means, such as friction of wood, long after flint and steel were understood. From this "new fire" all the lights to be used throughout the next year are supposed to be kindled. At Jerusalem the rush of the Eastern Orthodox pilgrims to light their candles at the newly created blaze has often made it necessary to employ soldiers to preserve order. Another reminiscence of the early necessity for extreme care in preserving fire is found in the Vestal Virgins who tended the undying fire in Rome. Elsewhere, as in ancient Peru, a similar custom is reported.

Worship and Sentiment.—While ceremonies connected with fire play at least a subordinate part in almost every religion, they sometimes become dominant. In the ancient Jewish religion and many others fire is the means whereby offerings are transmitted to the deity or to departed souls as among the Greeks. In many cases fire itself is worshipped, and often the worship of the sun can scarcely be distinguished from that of fire. The ancient Mexicans had a fire-god Xiuheuctli, closely related to the sun-god; the Kamchadals and Ainus of north-eastern Asia make fire their chief deity. Among more civilized people the ancient Assyrians, Chaldeans and Phoenicians practised fire-worship; Abraham was perhaps a reformer who refused to sacrifice his son Isaac in the consuming fire; the Israelites of later times were often scourged by their prophets for offering their children as sacrifices to Moloch, the god of fire. Among the ancient Aryans, if we may use so

indefinite a term, Agni (Latin *ignis*) was the chief god. Even to-day fire-worship is a notable feature of Hinduism, which is an offshoot of the old Aryan cult, and is the dominant factor in the religion of the Zoroastrians or Parsees. Among the oppressed remnant of the Parsees who still survive in the parts of Persia near Yazd and Kirman, and among many more primitive people, it is considered most irreverent to throw into the fire anything impure or disagreeable or to spit into it. The modern Parsees do indeed regard fire as merely a symbol, but in the beginning fire itself was probably the real object of worship. This is not surprising for there is probably no agency more powerful for good and ill, and motives of both gratitude and fear must have mingled in the minds of the early worshippers.

Although the worship of fire has largely disappeared in our day, its symbolism is still widely spread. The fire of love, the fire of ambition, are common similes.

Discovery of the Art of Fire Making.—In many of the legends which centre around the origin of fire, the interesting figure of the serpent-fighter occurs. The native Australians of Victoria say that a certain Karakorok, the good daughter of the good old man Pundyl, went abroad to kill the serpents which filled the land. Before she had killed them all, her staff snapped and a flame burst out of it. According to the ancient *Shahnama* of Persia, a hero called Hushenk hurled a prodigious stone at a snake; the snake escaped, but the stone struck a rock whereupon "light shone from the dark pebble, the heart of the rock flashed out in glory, and fire was seen for the first time in the world."

A North American legend states that the buffalo gave fire to man; as he raced in great herds across the plains at night, he lighted up the darkness with sparks and set the brush ablaze as his hoofs hit the rocks. The Dakota Indians replace the buffalo by a friendly panther which struck fire from its claws as it scampered up a stone hill. In South America the Quichés claim to have received fire from Tohil who produced it by shaking his sandals. His sign, like that of the Mexican god, Quetzalcoatl, is a flint. The vital point in all these legends is that the movements of men or animals cause stones to crash together, thus producing a spark which gives rise to fire. Such occurrences, together with his own experience in breaking rocks in order to discover which make the best tools, may have led some savage genius to discover that when flint and iron pyrites are struck together they produce sparks which will ignite dry grass or leaves. That mode of making fire is especially likely to originate in regions where rocks and dry grass are abundant.

In moist regions where the soil is so deep and the vegetation so dense that rocks are rare, or in places where flinty rocks are not present, another kind of natural occurrence is more likely to have helped in the discovery of fire. Now and again in the dry season two dead branches, rubbing together in the wind, become so hot that they ignite. Such accidents are not common, but during the hundreds of thousands of years of man's early development they presumably occurred often enough to be observed by men who possessed not only the ability and vision to see their significance, but also the curiosity and energy to make experiments.

Methods of Making Fire.—These two methods, percussion and friction, have always been the chief ways of making fire, but concentration of the sun's rays and the electric spark have also come into use. Friction has been by far the most widespread method among primitive people. In one of the simplest frictional methods the blunt end of a stick is rubbed back and forth along another piece of wood lying on the ground. The stick makes for itself a groove, and ultimately a spark is developed. This method formerly prevailed among the savages in New Zealand, Hawaii, Tonga, Samoa and elsewhere. In Tahiti Charles Darwin saw a native produce fire thus in a few seconds, but he himself succeeded only after long effort. In a somewhat more advanced frictional method the movable stick is rotated as rapidly as possible in a stationary piece of wood that lies on the ground. Such a fire drill, as it is commonly called, is sometimes rotated by rubbing the vertical stick between the palms of the hands. This device in one form or another has been observed among the primitive people in Australia, Kamchatka, Sumatra and the Caroline islands. It is

common among the Veddahs of Ceylon and in much of southern Africa as well as in large parts of both Americas. Various improvements have been devised in order to increase the speed of rotation. On the Pampas of South America the Gaucho formerly took an elastic stick about 18 in. long, placed one end in a hole in a stationary piece of wood, pressed the other to his breast, leaned down to bend the stick, and then rapidly turned the curved part like a carpenter's bit. A better method is to wind a string around the rotating stick or drill and pull it back and forth. In order to make it possible for one man to do this effectively, the Eskimos place the upper end of the drill in a socket of ivory or bone which can be held firmly in the teeth. Other Eskimos, as well as some Indians, fasten the two ends of the string to a bow and saw the bow back and forth. In our own day a device of this kind, with sawdust or some such material in the bottom of the hole to make the sparks catch quickly, is one of the first things taught to boy scouts. Still more ingenious than the bow drill is the pump drill of the Onandaga Indians. Here a string is fastened in such a way that when a small board is repeatedly pushed down the drill stick twirls rapidly, first one way and then the other. Many modifications of these methods are described and illustrated in the works of Tylor and Pauschmann.

In all the simpler frictional methods the two great difficulties have always been to create a spark and then to bring it into immediate contact with a sufficient amount of easily combustible tinder. In the most modern method—the match—both of these were first obviated by coating the ends of the movable stick with sulphur, which ignited at low temperature, and tipping the end with phosphorus which can be still more easily ignited by a single stroke. By the substitution of potash and non-poisonous forms of phosphorus for the earlier ingredients the modern safety match has at last been evolved as the latest successor of the two sticks rubbed together.

The method of making fire by percussion does not appear to have been of great importance until the Iron Age was so far advanced that steel was available. Its development was delayed by the difficulty in finding natural products such as pyrites which can be relied on to produce a spark when struck with a flint. After iron became common, the flint and steel became the best method of creating a fire. This method, however, was dominant for only a short time compared with the frictional method, for as soon as matches tipped with sulphur and phosphorus came into use (soon after 1830), it ceased to be of importance except in more backward regions. There it survives widely; in Central Asia flint-lock guns are still common.

Another method of making fire, namely, the concentration of the sun's rays by means of a lens or mirror, also belongs to a fairly high stage of civilization, but has never been used to any great extent. Aristophanes mentions a burning-lens in *The Clouds*; although the mirrors of Archimedes may not actually have set fire to the ships of the Roman besiegers of Syracuse, they show that the art of generating fire in this way was well understood. In Peru the sacred fire is said to have been kindled by means of a concave cup set in a great bracelet. In China the burning-glass has long been well known.

The latest important method of making fire is by means of the electric spark. According to one common device, a gas jet is arranged so that when it is opened an electric circuit is closed and then broken, and a spark passes through the escaping gas and ignites it. It should be noted in this connection that the intense heat generated by the electric current is beginning to displace fire not only in cases where an extremely high temperature is desired, but in various household appliances and elsewhere. This is only a partial displacement, however, for in most cases the electric current itself is generated by means of a fire in which coal is burned.

Fire and Material Progress.—When once the art of using and making fire became established, it must have altered human development in at least three ways. First, it must have stimulated the inventive faculty, thereby leading to material progress; second, it must have led to an increase in the density of population; third, it must have enabled primitive man to inhabit areas which had

previously been too cold. These three changes must have had a profound effect upon the location of the centres of civilization and progress, and perhaps upon the mental development of the various human races.

One invention commonly leads to another. Fire must have been peculiarly important in this respect. Although no exact knowledge is possible, we can infer with considerable certainty that after people once mastered what was then the extremely difficult art of using fire, it required only a moderate degree of inventiveness to make many other important discoveries. The primitive fire-users must soon have learned that sticks which are partly burned in the fire become pointed and hardened, thereby becoming more serviceable as weapons. Even if the effect of fire on food was not previously known, bits of flesh, green fruit, edible roots or other kinds of food must inevitably have fallen accidentally into the fire and been cooked as soon as fires became common. Their improved flavour and tenderness when rescued must have led persons with the keener type of mind to make experiments. The range of opportunities thus opened is enormous, for practically every growing thing which had the least semblance of edibility must have been subjected to the process of roasting. As time went on, and it became possible to heat water in skin bags by means of hot stones or in earthen vessels, the art of boiling food must have been discovered. At some time or other an earthenware jar which boiled dry, or some other accident must have suggested the possibilities of baking food by enclosing it within non-combustible receptacles. In our own day experiments in the use of fire for cooking are perhaps more numerous and vigorous than ever before.

Food is only one of the ways wherein fire obviously stimulated experiments. During the long period when the use of fire was known but the art of generating it unknown, the desire to create a blaze must have stimulated men's inventive faculties even more persistently than we are now stimulated by the desire to secure new and better sources of power. Again, having seen that animals are so averse to a blaze, he must have asked himself: "How can I best use fire to keep away animals during the night?" Then he presumably found that a flaming torch is a most effective weapon when thrust into the face of a wild animal. Thus the stimulus to invention must have gone on so that men discovered that fire-brands hurled into the huts of their enemies are a good weapon, or that when a patch of jungle is burned, the wild animals can be driven out and easily caught. In later days when civilization had advanced far higher, similar reasoning and experiment showed that flaming pitch, red hot balls of metal or explosive projectiles are effective ways of lighting fires in the midst of the enemy.

In connection with metallic ores fire has been a main agency in stimulating the inventive faculty. The first inkling as to the possibility of smelting presumably arose from the accidental melting of bits of ore in a hot fire. When once the significance of that fact was grasped by some genius, and when the highly valuable qualities of the resultant metals were realized, the stimulus toward melting all sorts of stones must have been enormous. Here, too, we see a line of experiments which has continued with increasing intensity to our own day. Thousands upon thousands of skilled inventors have worked upon the problem of making hotter and hotter fires. Thus we have melted more and more refractory stones, thereby enormously increasing the number of available metals and other valuable compounds. In this respect, as in many others, fire and its possibilities are still among the greatest agencies in stimulating human progress.

Greater perhaps than any of the preceding—or at least later and more striking in its effect—is the relation of fire to power. As soon as the first savage saw a yam or other bit of vegetation pop in the fire because steam was escaping, the principle of the development of power from fire was brought to man's attention. For hundreds of thousands of years thereafter many a boy presumably experimented by holding the lid down over a boiling vessel of water until the steam puffed it violently up. Many a man in addition to Hero, who made what was really a steam engine more than 2,000 years ago, must have realized that the expansive force of steam possesses energy which might be of high value. But only in modern times did progress along other lines finally make the

steam engine a practical invention. Then the attempt to use the energy liberated by fire suddenly gave an almost incredible stimulus to the world's inventive faculties. Our whole modern system of manufacturing, transportation, lighting and heating is based on the utilization of fire.

Pyrotherapy and Sterilization.—One of the most extraordinary features of fire is the way in which its use continues to increase even in our own day. This is especially true in the field of health. The value of cauterization in preventing harm from poisonous bites like those of snakes or mad dogs, and in preventing the spread of infection from wounds or sores has long been known, and was practised by the ancients. The value of hot baths in skin disease and in those of the joints has also been appreciated, at least since the days of the Romans. Only in modern times, however, have two other therapeutic uses of fire become known. One is the process of baking whereby a limb or other member is kept for a while at a temperature as high as it can endure with results which are said to be highly beneficial. The other is the use of fire for sterilization. The knowledge that heat, either in the form of flame or through the medium of steam or hot water, will kill bacteria has been one of the most revolutionary discoveries of modern times. To it, perhaps, as much as to any other single factor, is due the wonderful progress of modern surgery.

Dangers of Fire.—In spite of all the benefits derived from fire, the mere word "Fire!" is one of the most dreaded expressions in every language, for fire is as dangerous as it is useful. Some of the greatest disasters in all history have been fires such as those in Rome in the time of Nero, and the one which ravaged London for four days in 1666 and gave Sir Christopher Wren a chance to plan many important improvements. Chicago suffered a similar fire in 1871 and 100,000 people were rendered homeless; San Francisco experienced a similar fate after the great earthquake of 1906. Earthquakes have been the cause of some of the most terrible fires, as in Tokyo in 1923. There the style of architecture renders fires especially dangerous, for the houses are constructed of wood with paper walls and heavy thatch of straw. At Tokyo the fire killed 60,000 or 70,000 people, burned 25 sq.m. and drove away nearly 1,000,000 persons. In all countries the annual losses by fire are enormous. In England they amount to about £12,000,000 annually. In the United States, partly because wooden houses are more common than in Europe, the losses are far greater, amounting to over half a billion dollars every year from 1922 onward, and to \$560,000,000 in 1926, or approximately \$5 per person. In that same year the fear of fire led the people of the United States to pay \$635,000,000 in premiums to fire insurance companies, while \$352,000,000 was returned to cover losses. Forest fires are amazingly frequent and some of them lay waste thousands of square miles. From 1916 to 1925 the average number of such fires in the United States alone was about 51,000. Nearly half of these devastated at least ten acres; the average damage to trees and property amounted to about \$21,000,000, but the real damage was enormously greater because the fires kill the young growth, expose the soil to erosion, and alter the character and density of the new growth. In 1825 one of the greatest forest fires burned an area of 3,000,000ac. in Maine and New Brunswick, while fires that burned more than 1,000,000ac. in the United States and Canada occurred in 1853, 1871 (two totalling 3,280,000ac.), 1881 and 1910. Such fires may still occur in regions like Siberia, but are impossible in the more advanced countries because of the improved methods of fire-protection.

The Effect of Fire on Density of Population.—One of the most noteworthy facts in the history of civilization is the way in which many of the greatest inventions increase the density of population. Inventions connected with fire are pre-eminent in this respect. One of the first effects of the original discovery of the art of using fire must have been to increase the available food supply. It did this directly through the art of cooking, whereby many previously inedible or indigestible products became good articles of diet, and also by making it possible to smoke and preserve food that otherwise would have been wasted. Indirectly the use of fire still further increased the food supply by improving man's tools. It not only enabled him to use sharpened sticks as

described above, but helped him to break up the stones from which he procured flint implements, and kept him warm and dry so that he could work more effectively in cool weather. It enabled him to smelt metals and ultimately to make machines of all sorts. Thus fire has been a major agent in the process whereby man has multiplied his labour so that one man with the help of fire-made and fire-driven machinery can do as much work as scores or hundreds who have only their naked hands and no help from fire. In recent centuries no factor has exceeded the use of coal in fostering the growth and concentration of population; in earlier times the use of fire in other ways produced similar although less obvious results.

Fire and the Coldward March of Civilization.—One of the most extraordinary results of the use of fire is the way in which it has enabled the centres of human progress to move from warmer to cooler regions. According to the most recent studies the best climate for primitive savages without fire, clothing or shelter, is one where the temperature averages not far from 70° at all seasons, but yet has a fair degree of variability. The nearest approach to such a climate is by no means found in equatorial regions but at a distance of 25° or more to the north or south. Even there, however, although the winters are admirable, the summers are much too long and warm for the best health and greatest efficiency. Now man is so constituted that up to a certain point he can endure too much heat more easily than too little. Among naked savages, for example, a temperature of 90° is far less uncomfortable than one of 60°. Therefore unless people possess artificial means of warming themselves they tend to live in regions that are too warm rather than too cold. This retards progress, for people usually overcome the adverse effect of high temperature by inactivity rather than activity.

The introduction of fire changed all this. In conjunction with discoveries as to clothing and shelter, it enabled people to be comfortable in cool climates. Each new discovery meant a step away from low latitudes. The invention of the hearth to replace the bare ground as a place for a fire was one of the earliest reasons for such a step. The invention of a protected opening in the roof to carry off the smoke was another. Still another was the combination of the hearth with a chimney in such a way as to give an efficient draft, eliminate smoke and throw the heat out into the room; then came the enclosed oven or stove of mud as in China; later the stove of metal; then central heating by means of furnaces supplying hot air, steam or hot water and heated first by wood, then by coal, and lately by oil or gas. Each of these improvements in the use of fire, together with the corresponding advances in clothing and architecture, reduced the difficulties due to low temperature, for they helped to create an artificial climate in which people were approximately as comfortable, healthful and energetic as in the ideal climate. Thus to-day we can live comfortably and in good health in climates so cold that people without fire would perish.

One of the greatest benefits of man's conquest of fire has been that the human race has gradually been able to migrate into the cooler and hence more healthful and energizing parts of the world. At every stage of this process of expansion there has been a definite zone of highest comfort, best health and greatest activity. Beginning not far beyond the tropics, the zone shifted to Mediterranean lands, and then to higher latitudes. To-day it is coincident with the zone of greatest progress, highest civilization and world dominance, a condition which also appears to have been true in the past. A further advance in the use of fire may possibly carry the zone of greatest progress as far north as southern Scandinavia and southern Canada, but not beyond, for there the summers as well as the winters become too cool. The ultimate location of this most favoured zone will doubtless be the regions where the following three conditions are most nearly fulfilled: (1) the summer climate is ideal for civilized people who wear clothes and live in houses; (2) the use of fire creates ideal atmospheric conditions within doors during the rest of the year; and (3) the degree of variability arising from the weather on the one hand and the use of fire on the other produces the maximum stimulus, but does not injure health. With our present skill in the use of

fire a climate like that of London comes as near as any to satisfying these three conditions, but the regions surrounding Paris, Berlin, New York and Chicago do not lag far behind.

From all this it appears that the "coldward course of progress" as Gilfillan has called it, or the "northward course of empire" to use Stefansson's phrase, has depended upon the use of fire more fully than on any other factor that is yet clearly defined. It has involved a migration of the centres of power from regions where the winter climate is ideal but the summers debilitating, to those where the summer climate is ideal, and the disadvantages of the winter can be obviated by the use of fire together with clothing and shelter.

Fire and Racial Inheritance.—The possible biological effect of fire upon mankind ought not to be overlooked, although it is highly speculative. At first, and perhaps for many generations, the users of fire probably comprised only a small group of unusually intelligent, competent and progressive people. The first persons to use almost any revolutionary discovery are usually of that sort, no matter whether the discovery be the aeroplane, the electric motor, the art of weaving or the alphabet. During the long period when the technique of fire was new and crude its users must have had great need of intelligence, skill, patience and material prosperity, for otherwise they would not and could not have devoted to the art the many hours each day that must inevitably have been required. Among primitive hunters who are constantly obliged to change their abode it is by no means easy to maintain a fire that must never be allowed to go out, and the new arts of cooking and drying food and making fire-hardened weapons must also have been difficult. But the people who were sufficiently wise, active and patient to master all these difficulties must have reaped great advantages. Their food supply, as we have seen, became more abundant, more reliable and more nutritious, their improved weapons lessened the danger from both beasts and men, and their children must have enjoyed a freedom from hunger, exposure, disease and danger hitherto unknown. Such advantages, in a day when there was no such thing as birth control, must have caused the descendants of the fire-users to increase in number faster than did the people who lacked the wit, energy or resource to use the new invention. Thus, if there is any truth in the inheritance of mental traits, the inherent intelligence and progressiveness of the population must have been improved.

The degree of improvement must have differed from place to place. Near the equator the people presumably made little use of fire; the warmth of their climate not only prevented them from feeling much need of it, but made them loathe the necessary exertion. Thus in such regions fire had little effect in causing the intelligent people to increase in numbers. In the cooler parts of man's primitive habitat, on the contrary, the use of fire presumably caused the descendants of the more intelligent and progressive people to be numerous in proportion to those of the more stupid and indifferent, thus altering the average level of innate intelligence. Beyond the limits of the old inhabited area the use of fire enabled people to migrate into regions previously too cold for occupancy. Since all the migrants must have been of the intelligent fire-using class, whatever innate superiority they may have possessed must have been segregated and thereby perpetuated. Thus there must have been a gradation of innate ability from the unaltered people of the hottest regions to the selected new settlers in cooler regions. If such a differentiation occurred once, it must have occurred repeatedly when further progress in the mastery of fire enabled mankind to move into still cooler regions. The result would correspond exactly with the temperamental differences which now seem to be innate in the people of tropical as compared with temperate regions. All this is indeed speculative, but it ought not to be overlooked in considering the part played by fire in the development of mankind.

FIREARMS: see GUN and PISTOL.

FIREBACK, the ornamented slab of cast iron protecting the back of a fireplace. The date at which firebacks became common probably synchronizes with the removal of the fire from the centre to the side or end of a room. They never became universal, since the proximity of deposits of iron ore was essential to their use. In England they were confined chiefly to the iron districts of Sussex and Surrey, and appear to have ceased being made when the ore in those counties was exhausted. They are, however, occasionally found in other parts of the country, and it is reasonable to suppose that there was a certain commerce in an appliance which gradually assumed an interesting and even artistic form. The earlier examples were commonly rectangular, but a shaped or gabled top eventually became common.

English firebacks may roughly be separated into four chronological divisions—those moulded from more than one movable stamp; armorial backs; allegorical, mythological and biblical slabs with an occasional portrait; and copies of 17th and 18th century continental designs, chiefly Netherlandish. The fleur-de-lys, the rosette, and other motives of detached ornament were much used before attempts were made to elaborate a homogeneous design, but by the middle of the 17th century firebacks of a very elaborate type were being produced. Thus we have representations of the Crucifixion, the death of Jacob, Hercules slaying the hydra, and the plague of serpents. Coats of arms were very frequent, the royal achievement being used extensively—many existing firebacks bear the arms of the Stuarts. About the time of Elizabeth the coats of private families began to be used, the earliest instances remaining bearing those of the Sackvilles, who were lords of a large portion of the forest of Anderida, which furnished the charcoal for the smelting operations in early British iron-fields. To the armorial shields the date was often added, together with the initials of the owner. The method of casting firebacks was to cut the design upon a thick slab of oak which was impressed face downwards upon a bed of sand, the molten metal being ladled into the impression.

Firebacks were also common in the Netherlands and in parts of France, notably in Alsace. At Strasbourg and Metz there are several private collections, and there are also many examples in public museums. The museum of the Porte de Hal at Brussels contains one of the finest examples in existence with an equestrian portrait of the emperor Charles V., accompanied by his arms and motto. When monarchy was first destroyed in France the possession of a *plaque de cheminée* bearing heraldic insignia was regarded as a mark of disloyalty to the republic, and on Oct. 13, 1793, the National Convention issued a decree giving the owners and tenants of houses a month in which to turn such firebacks with their face to the wall, pending the manufacture by the iron foundries of a sufficient number of backs less offensive to the instinct of equality. Very few of the old plaques were however removed, and to this day the old châteaux of France contain many with their backs outward.

FIRE-BRAT, a small insect (*Thermobia domestica*) related to the silverfish (*q.v.*), and found in bakehouses, where it feeds upon bread and flour.

FIREBRICK. Under this term are included all bricks, blocks and slabs used for lining furnaces, fire-mouths, flues, etc., where the brickwork has to withstand high temperature (see BRICK).

The conditions to which firebricks are subjected in use vary greatly as regards changes of temperature, crushing strain, corrosive action of gases, scouring action of fuel or furnace charge, chemical action of furnace charge and products of combustion, etc., and in order to meet these different conditions many varieties of firebricks are manufactured.

A firebrick suitable for ordinary purposes should be even and rather open in texture, fairly coarse in grain, free from cracks or warping, strong enough to withstand the pressure to which it may be subjected when in use, and sufficiently fired to ensure practi-

cally the full contraction of the material. Very few fireclays meet all these requirements, and it is usual to mix a certain proportion of ground firebrick, ganister, sand or clay with the fireclay before making up. The fireclay or shale or other materials are ground either between rollers or on perforated pans, and then passed through sieves to ensure a certain size and evenness of grain, after which the clay and other materials are mixed in suitable proportion in the dry state, water being generally added in the mixing mill, and the bricks made up from plastic or semi-plastic clay in the ordinary way.

The proportion of ground firebrick, etc., used depends on the nature of the clay and the purpose for which the material is required, but generally speaking the more plastic clays require a higher percentage of broken firebrick or "grog" than the less plastic clays, the object being to produce a clay mixture which shall dry and fire without cracking, warping or excessive shrinkage, and which shall retain after firing a sufficiently open and even texture to withstand alternate heatings and coolings without cracking or flaking. For special purposes special mixtures are required and many expedients are used to obtain fireclay goods having certain specific qualities. In preparing clay for the manufacture of ordinary fire-grate backs, etc., where the temperature is widely variable but never very high, a certain percentage of sawdust is often mixed with the fireclay, which burns out on firing and ensures a very open or porous texture. Such material is much less liable to splitting or flaking in use than one having a closer texture, but it is useless for furnace lining and similar work where strength and resistance to wear and tear are essential.

Furnace Firebrick.—For the construction of furnaces, fire-mouths, etc., the firebrick used must be sufficiently strong and rigid to withstand the crushing strain of the superimposed work at the highest temperature to which the firebrick is subjected.

The wearing out of a firebrick used in the construction of furnaces takes place in various ways according to the character of the brick and the particular conditions to which it is subjected. The firebrick may waste by crumbling—due to excessive porosity or openness of texture; it may waste by shattering; it may gradually wear away by the friction of the descending charge in the furnace, of the solid particles carried by the flue gases and of the flue gases themselves; it may waste by the gradual slagging of the surface through contact with fluxing materials; in cases where it is subjected to very high temperature it will gradually vitrify and contract and so split and fall away from the setting. It is a well-recognized fact that successive firings to a temperature approaching the fusion point, or long continued heating near that temperature, will gradually produce vitrification, which brings about a very dense mass and close texture, and entirely alters the properties of the brick.

Where firebricks are in contact with the furnace charge it is necessary that the texture shall be fairly close, and that the chemical composition of the brick shall be such as to retard the formation of fusible double silicates as much as possible. Where the furnace charge is basic the firebrick should, generally speaking, be basic or aluminous and not siliceous, *i.e.*, it should be made from a fireclay containing little free silica, or from such a fireclay to which a high percentage of alumina, lime, magnesia, or iron oxide has been added. For such purposes firebricks are often made from materials containing little or no clay, as for example mixtures of calcined and uncalcined magnesite; mixtures of lime and magnesia and their carbonates; mixtures of bauxite and clay; mixtures of bauxite, clay and plumbago; bauxite and oxide of iron, etc.

In certain cases it is necessary to use an acid brick, and for the manufacture of these a high siliceous mineral, such as chert or ganister, is used, mixed if necessary with sufficient clay to bind the material together. Dinas fireclay, so-called, and the ganisters of the south Yorkshire coalfields are largely used for making these siliceous firebricks, which may be also used where the brickwork does not come in contact with basic material, as in the arches or other parts of many furnaces. It is evident that no particular kind of firebrick can be suitable for all purposes, and the manufacturer should endeavour to make his bricks of a definite com-

position and texture to meet certain definite requirements, recognizing that the materials at his disposal may be ill-adapted or entirely unsuitable for making firebricks for other purposes. In setting firebricks in position, a thin paste of fireclay and water or of material similar to that of which the brick is composed, must be used in place of ordinary mortar, and the joints should be as close as possible, only just sufficient of the paste being used to enable the bricks to "bed" on one another.

It has long been the practice on certain works to wash the face of firebrick work with a thin paste of some very refractory material—such as kaolin—in order to protect the firebricks from the direct action of the flue gases, and a thin paste of carborundum and clay, or carborundum and silicate of soda has been extensively used for the same purpose. So-called carborundum bricks have been put on the market, which have a coating of carborundum and clay fired on to the firebrick, and which have a greatly extended life for certain purposes. It is probable that the carborundum gradually decomposes in the firing, leaving a thin coating of practically pure silica which forms a smooth, impervious and highly refractory facing. (X.)

UNITED STATES PRACTICE

The classification of fireclay bricks used in America is as follows: high duty, fuses not lower than cone 31 (approximately 1,750° C); intermediate duty, not lower than cone 28 (1,690° C); moderate duty, not lower than cone 26 (1,650° C); low duty, not lower than cone 19 (1,510° C). The highest grade fireclay fuses at cone 35–36 (1,830–50° C). Bricks made from materials more refractory than fireclay are designated *super-refractories*.

Refractoriness.—The term firebrick intimates resistance to the softening effects of heat, but refractory brick is the better term. Firebricks must withstand metallurgical heats and resist the fusing action of slags. A silica brick is acid and is used in furnaces developing acid slags; lime, dolomite and magnesite (*qq.v.*), on the other hand, are strongly basic. Between these extremes every gradation occurs. A fireclay brick made from a siliceous clay is more or less acid, from pure clay slightly basic, from bauxite or diaspore (*qq.v.*) still more basic. Besides the basic and acid firebricks there are neutral bricks made from chrome ore. In an open hearth steel furnace, for example, the hearth may be built of dolomite or magnesite; then at the slag line a band of neutral bricks is built, upon which rests the silica brick crown.

The best American fireclays, *et seq.*, quartzite, bauxite, diaspore, cyanite and all calcined materials are without plasticity and to make them into bricks some kind of bonding material is required. A plastic clay in quantity of 10% and upward is most commonly employed to give the necessary plasticity, but in numerous products it is not suitable, so lime, tar, powdered slags, such as glass and cement, silicate of soda and other chemicals are used. In the designation of siliceous bricks there is considerable confusion. *Ganister*, the English term for a clay bonded sandstone brick, in America is called *quartzite* and in Germany, *Dinas*. The lime bonded silica brick in England is the *dinas* brick and in America the *silica* brick.

New Jersey, because of its fireclay deposits and its location on the early settled eastern coast, was the first locality in America to produce firebricks. It is said that a firebrick was produced in New Jersey as early as 1812, but there is no authentic record of this. In 1825 a factory was established in Woodbridge, N.J.; in Connecticut in 1835; in Pennsylvania in 1836; and in Maryland in 1839. The older grinding and pugging of hard materials with the wet-pan is being replaced by dry-pan grinding, and the wet-pan is used only for pugging. Pug-mills as used in other clay industries are not commonly used for soft-mud firebricks.

Dry-pressed Firebricks.—In 1886 at Union Furnace, O., firebricks of flint and plastic fireclays, and ganister rock, were made by the dry-press process (*see BRICK*), but because of the prejudice in favour of the hand-moulded product it was not commercially successful. More recently the dry-press has been introduced into many factories to supplement the soft-mud product and there are a number of factories that limit their product to

the dry-press process. Because of the high pressure given to the material by the dry-press a manufacturer is enabled to make bricks from a non-plastic material such as flint clay, magnesite, etc., with less, and indeed often without any primary bonding material. The dry-press has been especially useful in the manufacture of magnesite bricks.

Stiff-mud Process.—Until recently, except in the manufacture of special shapes and, in one or two instances, a *straight brick* product, the stiff-mud auger machine process (*see BRICK*) made no headway, but in 1928 a number of large firebrick factories were using this process. The clays are ground in a dry pan, pugged in a pug-mill, made into bricks through an auger machine, then re-pressed, dried in tunnel dryers, and finally burned in kilns, identically as in making other types of bricks.

Drying.—The early hot floors dryer consisted of a series of long covered ducts, each with a furnace at one end, connecting with a stack at the other end. This type of floor has given way to steam-heated concrete or iron floors, on the surface of which the brick are dried.

Burning.—The intermittent down-draft kiln is most widely used for burning firebrick. The round down-draft kiln is the favourite type and the more modern plants are so equipped. In 1928 the car-tunnel type was being widely adopted.

The latest Government bulletin (1926) available gives the following statistics:

	Annual output	
	Quantity	Value
Fireclay bricks, blocks, and tile in 9 in. standard equivalent . . .	1,007,784,000	\$40,013,394
Silica bricks	226,409,000	13,614,033
Magnesite and chrome	16,130,000	4,762,645
Other refractories	5,063,373
Special shapes in short tons (2,000 lb.)	61,909	1,714,914
Clay sold, raw and prepared, short tons	476,020	2,666,843

(E. Lo.)

FIRECLAY. Clay of highly refractory character, capable of resisting a very high temperature without fracture, fusion or softening. This quality is due to comparative freedom from fluxing impurities, such as soda, potash, lime, iron, and magnesia. There is no fixed standard of refractoriness for these clays, but no clay should be classed as a fireclay which has a fusion point below 1,600° Centigrade.

Fireclays vary considerably in chemical composition, but generally the percentage of alumina and silica (taken together) is high, and the percentage of oxide of iron, magnesia, lime, soda, and potash (taken together) is low. Other materials, such as lime, bauxite, etc., are also used for the manufacture of firebricks where special chemical or other properties are necessary.

Fireclays are abundantly distributed in Great Britain, mainly in the extensive coalfields. A typical fireclay is composed of 67% silica, 22% alumina, 2% oxide of iron, 2% potash, 0.5% magnesia, 0.5% lime, 5.5% water, 0.5% organic matter. *See FIREBRICK.*

FIRE CONTROL: *see GUNNERY, NAVAL.*

FIREDAMP, the most prevalent of the noxious and inflammable gases found in mines. The chief constituent of this gas is methane, also known as marsh gas (*q.v.*). Firedamp is commonly termed "gas" by the coal miner, and a mine in which its occurrence is common is known as a "gassy" or "fiery" mine. Firedamp is never found as pure methane in mines. Analyses in seams in the north of England made by Sir H. de la Beche and Mr. (afterwards Sir) Lyon Playfair in 1846 showed the gas to contain:—

	Percent	Percent
Methane	77.5	to 98.2
Nitrogen	1.3	to 26.1
Carbonic Acid	0.3	to 2.1
Oxygen	0.0	to 3.0
Hydrogen	0.0	to 3.0

Sometimes, besides methane, firedamp contains a small quantity of another highly inflammable gas, ethane (*q.v.*). Thus samples of mine atmospheres taken in a working place (a dip drift) at the Glückhülfe colliery at Waldenburg in 1881 and analysed by Dr. Poleck for the Prussian Firedamp commission, showed its composition to be as follows:—

	1. Percent	2. Percent
Methane (CH_4)	34.93	32.65
Ethane (C_2H_6)	2.89	3.99
Carbonic Acid (CO_2)	41.49	41.49
Carbon Monoxide (CO)	1.87	1.87
Nitrogen (N) }	20.69	20.00
Oxygen (O) }	100.00	100.00

The considerable quantity of carbon dioxide points to the sample being the result of decomposition. The carbon monoxide was discovered by the aid of the spectroscope. Methane is odourless, colourless and tasteless. It burns with a bluish flame forming carbonic acid and water. As it is lighter than air it rises upwards to the roof and is found in the higher parts of the workings. When mixed with air to the extent of 6.1%, the atmosphere becomes just ignitable, so that 6.1% is spoken of as the lower limit of inflammability; the most explosive mixture, however, is that which contains 9.47% of methane; that is, where there is present just sufficient methane to consume all the oxygen in the air. Eight to 14% may be regarded as the high explosive range. At 22% the mixture ceases to be explosive. Though firedamp is found chiefly in coal mines, where it exudes from the pores and cavities in the coal, its occurrence is not restricted thereto. In 1886 two explosions of firedamp occurred in the Mill Close Head mine at Darley Dale in Derbyshire, by which five persons lost their lives; its occurrence in metalliferous mines has also been reported. It probably occurs in all coal mines, though some are commonly described as exempt, *e.g.*, the coal mines of the Forest of Dean, but is probably generated in such small quantity as not to be detectable on the flame of a lamp or candle. The usual way of determining the presence of firedamp in the mine atmosphere is by the pale violet-blue "cap" above the flame of the safety lamp. It is detectable by this means when present to as low a percentage as $\frac{1}{2}$ (*see SAFETY LAMP*).

In some seams firedamp exists in a state of considerable pressure, as determined by the late Mr. (afterwards Sir) Lindsay Wood in experiments conducted by him in 1880 for the royal commission on accidents in mines. For this purpose holes were driven into the solid coal, plugged and fitted with a pressure gauge, when pressures as high as 461 lb. per sq.in. were obtained after some days. The greatest volume of gas given off was equivalent to 5,927 cu.ft. per hour. These, however, are abnormal figures. Sudden outbursts of firedamp, the *dégagements instantanés* of the Belgian miner, are an infrequent occurrence in British coal mines, usually taking place in the neighbourhood of a fault. "Blowers" of gas, the *soufflards* of the French miner, are more common, a blower being a stream of gas frequently accompanied by water, continuing at a constant pressure sometimes for years. (*See also COAL AND COAL MINING.*) (R. R.)

FIRE-DOG, one of a pair of supports for wood that is burned in an open fireplace (*see ANDIRON*). It has an upright standard to which is attached a horizontal bar which raises the logs above the hearth level. The spreading base gives the support an appearance similar to that of a dog, hence fire-dog. Various materials are used, such as cast-iron, wrought-iron, steel, brass and cast-brass. Wrought-iron fire-dogs, with little or no ornament, were used in the simple homes, whereas the more expensive materials, with every conceivable adornment, belonged to the élite. The 17th century was noted for its rich and elaborate andirons, some of which stood 4 ft. high and were tipped with such decorations as bronze discs, shields of arms and statuettes.

FIRE ENGINES. The modern "fire engine" (also termed "motor pump") has a petrol power unit driving a pump which takes suction from a water supply and forces the water through lines of flexible hose to nozzles from which streams are directed upon the flames. In most cases, the engine is in the form of a motor vehicle having a four or six cylinder internal combustion motor

of the usual type, but designed for the most severe kind of heavy duty service, the motor being employed not only to propel the apparatus along the road, but also to drive the fire pump when required, while the vehicle itself remains stationary. (*See INTERNAL COMBUSTION ENGINE.*)

Such a vehicle is usually provided with a body for carrying hose and may be equipped also with ladders, pike poles, fire axes, crow-bars, lanterns, hand fire extinguishers, nozzles, chemical fire engines and other accessories. In the larger cities fire-fighting equipment may also include ladder trucks which carry ordinary ladders as well as aerial ladders that are permanently attached to the vehicle and may be raised or lowered by a mechanism on the ladder truck. Water towers somewhat similar to the aerial ladders may also be used. High pressure fire engines have been developed to deliver water to the upper floors of high buildings in large cities.

History.—The earliest method of fighting fires consisted of throwing water on the fire from buckets or other vessels. It is not known what fire-fighting facilities were available at the time of the burning of Rome in A.D. 64. The first use of a device for applying water on to a fire in the form of a stream dates back as far as the 2nd century B.C. The science of fire extinction was still in a very elementary stage in the year 1666, when the great fire of London occurred. The only fire engines, used at this fire were those of the hand-operated type. The early squirting devices were usually in the form of a mammoth syringe. This later developed into a receptacle for holding water which was filled and replenished during the fire by a bucket brigade, the water being withdrawn and ejected by means of an early form of pump.

The pumps on the early fire engines were hand-operated and the range and force of the stream were poor. In many instances the engine was destroyed by the fire owing to the fact that the short range of the stream made it necessary to take the apparatus close to the flames. This led to the development of better pumps which could squirt a much longer distance. Subsequently, the development of a flexible pipe or hose made it possible to locate the engine well away from the fire and to convey the water under pressure from the engine to the fire. A still later development

was the employment of suction hose to enable the pump to feed from other sources other than its own suction.

Steam Fire Engines.—The first mechanically operated fire engines appear to have been developed early in the 19th century when steam was first used for operating a fire pump—the vehicle on which the pump and steam boiler were mounted being drawn to the fire either by the firemen or by horses. About 1860 steam fire engines were being made in England and the United States. Public interest in steam fire engines was greatly stimulated by competitions held in England at the Crystal Palace in 1863, in which engines from the United States took part.

Steam fire engines were used almost exclusively at the Chicago,

III, conflagration in 1871. Toward the end of the 19th century horse-drawn steam fire engines had been brought to a state of high perfection both in Europe and in the United States, when engineers began the development of the self-propelling vehicle. The earliest self-propelled machines were those of steam fire engines.

Motor Fire Engines.—The first self-propelled fire engines employing an internal combustion motor (other than as a tractor) were built about 1903. By 1910 a considerable number of motor fire engines were in successful service in various parts of the world and in 1928 practically every large city in the United States and many of the large cities in Europe had discarded horse-drawn and steam fire engines, in favour of self-propelled motor fire engines. However in some cases the old horse-drawn and steam fire engines are still sometimes used as reserve equipment. Normally, a motor fire pump chassis is very strongly constructed in view of the fact that a fire engine is heavy and necessarily has to travel at high speed.

Various types of pumps are employed. The rotary gear type is a positive action pump which will draw its water from a depth of 20 to 25 ft. without being primed. The centrifugal pump is also employed but as this has no power of suction in itself it is either fitted with some form of priming device or with an auxiliary positive action pump for suction purposes. Piston pumps are also used and are very satisfactory under some conditions. In some cases a shaft is placed in line with the motor shaft which is used to drive the pump as well as the vehicle, through the use of separate transmissions.

Chemical Fire Engines.—These engines may be a part of a motor fire engine or may be mounted separately on a motor vehicle either alone or in combination with a body for carrying hose or other equipment. Chemical fire engines are of two types: soda-acid and foam. The soda-acid engine consists of one or more cylindrical vessels charged with a solution of bicarbonate of soda dissolved in water. Enclosed in this cylindrical vessel is also a receptacle for holding a quantity of sulphuric acid. A hose line generally $\frac{3}{4}$ or 1 in. in diameter is connected to the outlet of the cylindrical vessel and when the chemical engine is required for use, the sulphuric acid is caused to be discharged from its receptacle into the bicarbonate of soda solution. This admixture of the acid with the soda solution within the cylindrical vessel forms carbonic acid gas under pressure, which forces the solution through the hose. In the soda-acid machines various methods for causing the acid to be discharged into the soda solution are employed: (1) inverting the acid bottle by means of an operating handle; (2) revolving the cylindrical vessel on its trunnions, thus inverting the acid receptacle. The invention of these chemical fire engines has been especially helpful in fighting fires where there is a shortage of water, a problem which must often be faced in the out of town districts.

The foam chemical engines are a development from the soda-acid chemical engine. The foam type of machine is somewhat similar to the soda-acid excepting that the acid ingredient is a solution of aluminium sulphate dissolved in water. The admixture of aluminium sulphate solution with bicarbonate of soda solution produces a froth, but its bubbles are very easily broken down. To make the bubbles tougher and more stable a stabilizing ingredient is added to the bicarbonate of soda solution. The discharge from a foam chemical engine is therefore a tough and tenacious foam made up of minute bubbles containing carbonic acid gas. This foam has the property of adhering to any burning solid surface upon which it is thrown and will even adhere to a vertical wall or to a ceiling; it also floats on any inflammable liquid. This foam completely excludes air from the surface which it covers and deprives the fire of the oxygen which would otherwise feed the flames, thus extinguishing the fire by suffocation. In the foam chemical engine as used on motor fire apparatus the two solutions are forced into two separate hoses which are joined together at their end into a common nozzle. The usual method of forcing the solutions from their vessels into the hose is by means of an inert gas contained in a pressure cylinder or by means of separate pumps. A more recent development of the

foam chemical method of fire extinction consists in dispensing with the solutions and using the chemicals in their dry form. With this method a so-called foam generator is employed. A water supply under pressure is connected to one end of the generator and discharge hose at the other end. The dry chemicals are poured into the hopper of the generator as required at the time of fire. As the stream of water passes through the generator it automatically draws the dry chemicals into the water stream, resulting in chemical action by means of which foam is discharged from the nozzle.

Fire Boats.—A very important feature of the fire-fighting equipment in large river, lake and sea ports is the fire boat. They are essentially large tug-boats equipped with fire pumps of 3,000 to 12,000 gal. capacity. The older boats were steam-propelled and the pumps steam-driven. The newer boats are propelled by internal combustion motors such as the very efficient Diesel engine which are not only employed to propel the boat but also utilized to drive the fire pumps when required. A boat recently built has a pumping capacity of 12,000 gal. of water per minute at about 100 lb. pressure, is 123½ ft. long, 26 ft. beam and 7½ ft. draught, and has been designed to travel at a speed of about 14 knots per hour.

Fire Extinguishers.—It is not uncommon for motor fire apparatus to carry fire extinguishers of the soda-acid or foam type which are variants of the chemical fire engines described above and small enough so that they can be carried into a burning building by the fireman. Fire apparatus may also carry fire extinguishers of the carbon tetrachloride type which are particularly useful in connection with fires in electrical generating stations, etc., owing to the fact that the fluid is a non-conductor of electricity. (J. H. Os.; C. B. R.)

FIRE ESCAPES in England refer to constructing ladders mounted on wheels which are intended to be used exclusively for the purpose of enabling people to escape from burning buildings. Abraham Wivell invented the first portable fire escape ladder of this kind about 1837. Before Wivell's time, however, various smaller fire escapes were in use. There is in existence a very interesting drawing by C. Geissler, dated 1789, showing three types employed in Geneva at that date, consisting (a) of the cloth or canvas "chute," (b) the rope and basket (or sling), and (c) sectional ladders fitted with sockets so that several could be joined together to make one long length, the top section having running wheels to travel easily up the walls of a building. Sectional ladders of somewhat similar build were the first fire escapes to be used in London, when John Braidwood, the famous first Chief of the London Fire Engine Establishment, put them into service there in 1832. They were made in short lengths of about 6 ft. for carrying upon the fire engines of the period.

Wivell's wheeled fire escape was not officially adopted, though it was put into service in London by the Royal Society for the Protection of Life from Fire. A few years later another type of wheeled escape known as the "fly-ladder" was evolved and this, being an improvement upon Wivell's machine, gradually superseded it. The "fly-ladder" had a main ladder about 35 ft. in length mounted upon a spring carriage, with large wheels. At about 10 ft. from the top of the main ladder a folding ladder of about 20 ft. was joined by hinges, and was raised when required for use by ropes attached to projecting levers. It was possible also to detach this folding ladder when required; and in the event of greater heights having to be negotiated than the combined height of the main and fly-ladders, a separate short ladder was placed at the top of the folding ladder, and by this means a height of about 60 ft. could be reached. At the under-side of the ladder was affixed a canvas chute protected externally by copper wire netting; this was used to pass persons down when it was possible to get the top of the chute upon a suitable window-sill. For greater heights the persons had to be carried down the ladders in the same way as is done in the present day.

Telescopic Escapes, 1890.—The fly-ladder escape held the field in England until about 1890, when telescopic escapes were introduced embodying the sliding body principle, which enables the ladders to be carried in a horizontal position and elevated to the

vertical on arrival at a fire. These ladders were arranged to slide in a framework attached to the axle, and were held in position by means of hand-driven gear arranged on the backfly. They could be pitched at any angle to the building, thus enabling a wide forecourt to be bridged, which could not be done with the older types of fire escapes; but it was found that for service of this kind it was necessary to strengthen the sides of the ladders, and in 1896

BY COURTESY OF MESSRS. MERRYWEATHER AND SONS, LTD.

A MODERN FIRE LADDER THAT CAN BE USED AS A WATER-TOWER
It can be raised 90 feet into the air, and adjusted to any position by one man in less than one minute. It is equipped with loud-speaker telephones

J. C. Merryweather patented a system of bowstring girder trussing which also formed a convenient hand-rail on each of the ladders. Other makers, notably Shand Mason & Co., introduced other forms of trussing to achieve the same object. Soon after these sliding carriage escapes were introduced the motor system began to make headway in service, and it became customary to arrange brackets at the rear of the motor vehicles to carry fire escapes, which could then be dismounted upon the arrival of the engine at a fire, and wheeled by hand to any convenient position for use. This is still the practice in most large British fire brigades. Before arriving at this stage of development, however, there had been an intermediate stage when sliding carriage fire escapes were carried upon horse vehicles, some being of the dog-cart pattern, and others being four-wheeled horse drawn vehicles generally known in the service as "tenders." Many fire brigades now carry light trussed ladders (35 to 40 ft. dismantled ladders) in an overhead position on their motor vehicles; these are very serviceable where buildings of moderate height are concerned.

Another form of escape which, although introduced many years ago, is still popular, is the "pompier" ladder; as its name indicates, it is of French origin. It is an exceptionally light ladder usually from 16 to 18 ft. in length, and at the end an iron or steel hook is fixed for the purpose of reaching over and holding on to window-sills. In expert hands the pompier ladder is very useful, but it can only be safely worked by trained firemen. It is not always employed in the ordinary way as a fire escape, but is used for the purpose of enabling firemen to scale walls of burning buildings, and persons to be saved are lowered to the ground by ropes which the firemen carry.

Recent Methods.—In Great Britain and on the Continent of Europe, the most modern type of fire escape is that known as the "turntable" ladder. It is mounted upon an automobile chassis, and, the ladders can be slewed round to any required position. A good example is a machine built at the end of 1927 for the Leicester Fire Brigade. The chassis has a six-cylinder engine of 60 B.H.P., which not only provides the power for road travelling but also, through special gearing, elevates, extends and revolves the ladders, so that they can be moved into any desired position. The movements of the ladders are controlled by three levers, and a graduated quadrant shows automatically the angle of elevation, while an indicator gives the height of extension. Plumbing gear is provided to enable the ladders themselves to remain vertical even when the carriage is standing on uneven ground. At the top of the

ladders is fitted a swivelling monitor nozzle, for use as a water tower, from which a jet can be sent in any direction. Upon the turntable platform is a powerful searchlight which will throw a beam up the ladders whatever their position may be, thus lighting up the man who is controlling the jet or effecting a rescue; and this man is in communication, by means of a loud speaker telephone, with his comrades on the ground. In the centre of the chassis is fixed a "Hatfield" fire pump, capable of delivering 250 gal. per min., and at the top of this pump is mounted a monitor swivelling nozzle from which a jet can be thrown direct upon a fire. The delivery of the pump is also arranged in such a way that the water can pass up through hose carried up the ladders for the purpose of attacking the fire from above, by means of the water tower just mentioned. It will be seen that it is possible for this machine to be used as a water tower and fire engine simultaneously, since the pumps can be working on the main monitor which is mounted upon the pump itself, while the ladders are being used for rescue purposes.

Every possible precaution has been taken to secure safety in operation. Trussing is employed to increase the strength of the ladders, and an ingenious device ensures that when either of the three controlling levers are released by the operator, no matter at what angle or extension the ladders may be, the power is cut off and the ladders remain absolutely secure. Again, if either of the levers is pulled down, or kept down too long, over-elevation or over-extension is automatically prevented by a device which forcibly returns the levers to the free position before the point of danger is reached. The outstanding feature of this machine is that, contrary to the practice in some of the earlier types, the one engine performs every operation. This system was patented by Merryweathers' in 1908, and although in the interval many machines have been built in which the movements of the ladders were controlled by a separate motor, the use of the main engine for all purposes is now practically universal, Continental makers having followed English practice.

Motor turntable ladders are built in various lengths, but as they are expensive machines it is the general practice to construct them to command very considerable heights. The longest ladder of this type built up to the year 1928 was one made by Merryweathers' for the Cairo Fire Brigade in 1926, which is capable of reaching a vertical height of 95 ft. from the ground level.

The fire ladder is usually equipped with revolving screws which raise or lower the ladders round a pivot. Steel cable is used for extending the telescopic ladders. Bracing rods are provided to stiffen the ladders when in use. In the accompanying diagram may be seen the nozzle of the "water tower" and the revolving platform on which the mechanism and ladders are mounted.

These are the principal types of escapes in general use by public fire brigades, but of course, many smaller appliances, or domestic escapes, are used independently of the assistance of trained firemen. These range from a simple knotted rope, and a plain rope with a fluffy surface to avoid chafing the hands, through various types of rope ladders, iron folding ladders, etc., to the most popular form of all, the canvas "chute" fire escape. Such patent self-help fire escapes, which are many, do not, however, come within the scope of the present article. (J. H. Os.)

THE UNITED STATES

In America the term "fire escape" is seldom used in the sense in which it is used in England. American fire apparatus analogous to that of the English fire escape is discussed elsewhere in another article. The term fire escape in the United States is restricted in a narrow sense to the railed balconies with iron stairways which give access from storey to storey in time of emergency. These fire escapes usually lead from the roof to the street. Such fire escapes will be found everywhere, except in the smallest towns. Nearly every city has minute rules covering fire escapes, the regulations being promulgated by the fire department, the building department or the tenement house department. In this article attention is not confined to this type of escape, but is also directed to the building exit in a broader sense, which conforms to the building codes of most States and cities. The problem of proper exits is related to alarms and fire-drills where factories are con-

sidered. The ordinary iron fire escape has proved a snare on so many occasions that its real value is doubted by many authorities. Where the access to it is gained through metal doors, or wire-glass windows in metal frames, and where there is no opening directly against the ladder portion this type of escape is effective. Fire and smoke coming through windows make many fire escapes impassable, except for trained firemen.

Regular outside stairways give better protection for factories, but are not recommended for buildings over six storeys high. Wherever possible, the stairs should be placed against a blank wall. High railings filled in with wire mesh give a feeling of security. No encumbrances should be placed on the platforms or stairs, and entrances should not be through private offices or wash rooms. In winter the steps and platforms should be kept free from snow and ice; for the escape may be needed any minute. The lower portion of the smaller fire-escapes often consists of a ladder; but a counterweighted section of the stairs is better practice. Straight and spiral chutes are sometimes used and are valuable for the rapid evacuation of a building. Poles are in use in powder factories, but they are not adapted for general use. Fire escapes are designed to carry a safe load of 100 lb. per sq.ft., with a factor of safety of six.

The best fire escape is a "smoke-proof tower," where each exit from the occupied floor gives access to an open air vestibule, or outside balcony, which, in turn, leads to a portion of the building separated by a fire wall which serves to enclose a platform and fireproof stairs. This tower cannot be obstructed by smoke from a fire on a lower floor. As such stairways must be reached from each floor by means of an outside balcony they are not generally suitable for every-day use. Such fire towers are in use in many office buildings. The interior enclosed stairway, if surrounded by fire-resisting walls or partitions and the entrance to each floor being protected by a fire-door, affords an efficient fire-exit for every-day use. They are not quite as safe as the smoke-proof tower, but a combination of both is excellent. Both types are lighted at all times by a current from an independent circuit. In summer hotels, rope fire escapes were formerly frequently used but this practice has largely disappeared.

FIREFLY, a term popularly used for certain beetles (*Pyrophorus*) on account of their power of emitting light. The insects belong to the family *Elateridae* (see COLEOPTERA). The genus *Pyrophorus* contains about 90 species, and is confined to America and the West Indies, ranging from the southern United States to Argentina and Chile. Except for a few species in the New Hebrides, New Caledonia, and Fiji, the luminous *Elateridae* are unknown in the eastern hemisphere. The light proceeds from a pair of conspicuous, smooth, ovoid spots on the pronotum and from an area beneath the base of the abdomen. Beneath the cuticle of these regions are situated the luminous organs, consisting of layers of cells which may be regarded as a specialized portion of the fat-body. Both the male and female fireflies emit light, as well as their larvae and eggs, the egg being luminous even while still in the ovary. The inhabitants of tropical America sometimes keep fireflies in small cages for purposes of illumination, or make use of the insects for personal adornment. Some cases have been observed of large numbers of fireflies flashing in unison. The function of the flashing is probably to facilitate the meeting of the sexes. The name "firefly" is often applied also to luminous beetles of the family *Lampyridae*, to which the glow-worm (*q.v.*) belongs.

FIRE INSURANCE. Fire insurance is an economic service which distributes over a large part of the community fire waste which might cripple the immediate sufferers and provides an atmosphere of security against catastrophe. By operating on a sufficient scale the insurer is able from the contributions of the many to make good the losses of the few and to the individual the ever-present risk of fire loss is replaced by a relatively insignificant payment.

Fire insurance may be said to date from the Great Fire of London (1666). The widespread havoc wrought by this disaster created a demand for protection, and the remaining years of the 17th century saw the formation of several companies for this purpose. Without experience to guide them their operations were largely experimental, but the enterprise succeeded and at the beginning of the next century more companies were formed, some of which still exist.

Abroad progress was not so rapid and it was not until the middle of the 18th century that fire insurance appeared in Germany and North America. In France the first company formed was in 1816 and in Russia 1827.

Throughout the 18th century development in England was steady in spite of an increasingly heavy Government duty and further companies were formed soon after 1800. Sufficient experience had now been accumulated to put the business on a scientific footing and the offices began to pool their results to obtain a more accurate basis for the calculation of rates; this led, in 1858, to the formation of the Fire Offices Committee. In London the fire extinguishing appliances of the companies were also combined into a brigade for common protection. In 1865 the appliances were taken over by the municipality and formed the nucleus of the London Fire Brigade. In 1869 the Government duty was reduced to a nominal amount. In 1909 the Assurance Companies Act was passed. The principles which govern fire insurance in Great Britain have not been laid down by statute but have developed from cases decided in the courts.

Insurable Interest.—Any person wishing to insure property against fire must have an insurable interest in it, which has been defined somewhat as follows:—"That he shall stand in such lawful relation to it that he will be benefited by its preservation or prejudiced by its loss." The importance of this is readily apparent, as without it fire insurance might become a gamble with the consequent inducement to incendiarism and other evils. The interest must exist at the time of insuring and at the time of any claim.

The definition quoted above is wide enough to include more than simple ownership and among others the following may have an insurable interest:—

Mortgagees (since their security may vanish or be impaired).

Tenants (either for life or who may, under their lease, be responsible for loss or damage).

Bailees or persons who have charge in any capacity of the goods of others. (They may accept liability for loss under a contract or custom of a trade or negligence may be proved against them or their agents.)

Persons taking charge of goods for repairs, etc., have also a lien on them for work done and this they may also insure. Special classes of bailees are pawnbrokers (who are liable for fire loss under the Pawnbrokers Act, 1872), common carriers and innkeepers (whose respective liabilities at Common Law are limited by the Carriers Act of 1830 and the Innkeepers Act of 1863).

Trustees may insure the trust property. A bona fide interest, however slight, is insurable, but an expectation, however strong, is not.

Good Faith.—Fire insurance is a contract of the utmost good faith (*uberrima fides*) as opposed to an ordinary contract where the parties, in the absence of actual fraud, must protect themselves.

The duty of good faith devolves equally on the insured and the insurer but operates mainly for the protection of the insurer, who must usually rely on the information given him. A contract of fire insurance is void if the insured has failed to disclose any fact that would influence the insurer in his estimate of the risk involved. This is called a "material fact" and it is no defence that the insured did not know it as such. Whether a fact is material or not will depend on the circumstances of the case, but in practice the position is modified by the insurer submitting a list of questions to be answered and sometimes by his inspecting the property to be insured. It is sufficient if the information given by the proposer is substantially correct, but any fact that appears on the policy as a "warranty" must be literally accurate, and the business of insurance, on the wide scale practised to-day, would be impossible were this provision not respected.

Indemnity.—Fire insurance is a contract of indemnity, which is to say that the insured, after a fire, shall be in such a position that he is neither better nor worse off than before (subject, of course, to adequate insurance). This principle is vital, as to allow a man to profit from the destruction of his property would be an incentive to arson and contrary to public interest.

A logical extension of the principle of indemnity is that of Subrogation which is the right of an insurer who has paid an indemnity to stand in the place of the insured when there exists a right of action, arising out of a fire, against a third party. In such a case the insured has the choice of claiming from the insurer or the offending third party, and the former is usually the easier course. He must then allow the insurer, at his own expense, to prosecute the claim against the party responsible. Should the insured for any reason, such as under insurance, fail to recover the full amount of the loss from the insurer, the latter may only benefit from the third party claim after the balance of the loss has been made up.

BRITISH PRACTICE

Fire insurance in Great Britain is subject to remarkably little legislation and has been allowed to develop along its own lines.

The Assurance Companies Act (1909) stipulates that a deposit of £20,000 must be made by companies commencing business after that date, but a deposit is not necessary for fire insurance if one has been made for any other class of business. Accounts must be prepared in a specified form and submitted to the Board of Trade within a prescribed period. The remainder of the act has but little bearing on fire insurance. By the Metropolitan Fire Brigade Act (1865) companies insuring property in the City of London must contribute at the rate of £35 per £1,000,000 insured towards the expenses of the brigade.

Organization.—Fire insurance in Great Britain is mainly conducted by large "composite" companies, that is, companies dealing with several classes of insurance. They have usually a head office in London or a large provincial town and branch offices in the more important towns, each of which controls the agents in its area. Agents are remunerated on commission and are not empowered to sign policies. Beside the big composite companies there are a number of *mutual* companies (usually confining their operations to a special trade or business) and the members of Lloyds.

The majority of British fire insurance companies are members of the Fire Offices Committee, an association formed and controlled by the member companies for the pooling of experience and fixing adequate rates for important classes of property. Other branches of the committee's activities deal with standards for fire-resisting materials and construction, extinguishing appliances, commission and agency arrangements, etc. The London Salvage Corps is maintained by the fire insurance companies and attends outbreaks with the special object of reducing loss to property by expert treatment of damaged merchandize, disposal of water, etc.

The Policy.—Before accepting property for fire insurance the company usually requires the proposer to complete and sign a proposal form. This form is a list of questions designed to elicit a full description of the property to be insured, the insurance record of the proposer, etc., and correct answers are of the utmost importance, as they form the basis of any subsequent contract. If further information is required the company may send a surveyor to inspect the property.

The policy is the formal expression of the contract, which it sets out in detail. It bears a sixpenny stamp and is signed for the company by a director or other authorized representative. On the face of it appear the perils insured against, which are usually fire (with certain exceptions, such as fire caused by war, earthquakes, etc.), lightning, explosion of boilers used for domestic purposes, and explosion of gas used for lighting or heating or other household purposes in any building not forming part of a gas works.

It is further declared that the company have the option of reinstating the damaged property instead of making a payment and that the contract is subject to the conditions printed on the back of the policy.

A standard form of conditions is in use by most of the companies and the salient points of these may be summarized as

follows:—

Misdescription. Any material misdescription of the property insured or concealment of material fact invalidates the policy.

Increase of risk, transfer of interest or removal of the property. In these cases the insurer must be notified and his consent to the alteration endorsed on the policy, otherwise the policy is void from the date of the change.

Excepted goods and perils. Certain special classes of property, such as money, stamps, securities and documents, plans and models are not covered by a general description but must be specially mentioned. Explosives and goods in trust must also be specified and damage by explosion (except as stated on the face of the policy) is not covered. (This must not be confused with *fire* damage caused by explosion, which is covered.)

Notice of claim and proof of loss. Notice of loss must be given immediately and a detailed claim submitted within 30 days. The insured must, if required, furnish reasonable proof of loss.

Fraudulent claim invalidates the policy.

Reinstatement. Should the company elect to reinstate the insured must give them reasonable assistance in the form of plans, specifications, etc. Reinstatement need not be exact but only reasonably sufficient and is limited to the sum insured.

Right of entry. The company are authorized to enter and take possession of premises which have been the scene of a fire likely to give rise to a claim and to take possession of and deal with insured goods in a reasonable manner. In doing so they do not admit liability but obstruction by the insured invalidates the policy. (This condition appears rather drastic but considerable discretion is used in its application. Its intention is to allow the company to minimize the loss by prompt treatment of damaged goods and to investigate details of suspicious outbreaks before they can be obliterated.)

Contribution. If the property is insured by more than one company the liability under this policy is limited to the proportion which the insurance bears to the total, i.e., the insured must claim on all his insurers instead of selecting one or more.

Subrogation. This condition sets out the rights of the company under this heading (*see* INDEMNITY).

Arbitration. All differences arising out of this policy must be submitted to arbitration and an award made before action in the courts is taken. (This tends to reduce expensive litigation.)

FIRE INSURANCE IN THE UNITED STATES

The outstanding feature in fire insurance in the United States of America is the extent to which the business is Government controlled. The control is vested in the 48 State Governments, and their regulations and requirements vary considerably. Certain features are, however, common to most of them. A company must make a deposit and obtain a licence in each State in which it wishes to operate. Each State has its own form of policy conditions, usually based on the New York standard form but with minor differences. An annual statement of operations, in considerable detail, must be filed by each company and a periodical audit is conducted by the State insurance commissioner.

The supervision of the State extends to rates of premium and each company must file with the State Rating Office a schedule of rates covering every risk in the territory, which can only be altered by permission. Such a schedule is necessarily complicated and its application to single risks involves considerable labour and expense, so that usually all the companies operating in the State combine to share it. A system of rates is agreed upon and a rating and inspection bureau is set up, whose function it is to work out, on demand, the standard rate for any single risk, an inspection being made if necessary. Several organizations are maintained by the fire insurance offices for the collection of technical and statistical data, the most important being the National Board of Fire Underwriters. The organization of a fire insurance company differs somewhat from English practice. The larger areas involved have resulted in wider powers being given to local agents who are allowed to sign policies. Control of agency organization for a large territory is often vested in a general agent, instead of a branch, his remuneration being an over-riding commission on the business

done in his area. Special agents are company officials who maintain contact between the agents and the head office. The meticulous State control, the enormous areas covered and the wide range of climatic and occupational conditions make fire insurance in the United States a highly specialized service, calling for an unusual degree of technical efficiency.

FEATURES OF INTEREST IN OTHER COUNTRIES

Fire insurance outside of Great Britain and the United States is conducted on similar principles but offers some interesting modifications in practice. In many countries the business is regulated by sections of the commercial code and there is often a national form of policy conditions. In one or two countries, notably Uruguay and Costa Rica, the Government undertakes fire insurance, while in others such as Brazil and Mexico, insurance on property in the country may not be effected abroad. A characteristic feature in France and Belgium is the inclusion in the contract of various civil liabilities under the code of Napoleon. Policies in these countries are usually issued for ten years, with annual payments of premium, and fines are imposed if the insurance is not continued for the full period.

British fire insurance companies do a large business abroad and there are few countries where they are not represented. In the Dominions and India branches are often established but normally business is conducted through agents, who have full powers to issue policies and in all respects act for their companies. Supervision from the head office can only be exercised after considerable delay and the reliability of the agent is of the utmost importance both to his company and the prestige of British insurance. In many countries a deposit must be made and income tax is payable on profit earned. A considerable amount of insurance is effected in England on British undertakings abroad and there is a large market in London for foreign fire insurance of all kinds.

Insurance Against Loss of Profits Following Fire.—This form of insurance is designed to give protection against reduction or extinction of profits and the continued payment of standing charges when a business is wholly or partly stopped after a fire. Alternately an increase in the cost of running the business will be met providing it does not exceed the full amount of the profit and standing charges.

A profits policy provides for a specified "period of indemnity" which is the maximum time after a fire during which the loss of profits, etc., will be made good. This period, usually six to 12 months, is decided by the insured and should represent the maximum time necessary to restore the business to full activity.

The sum insured should then be ascertained on the basis of the net profits and standing charges for a similar period up to the end of the last financial year, provision being made if necessary for an expansion of business. The proposer must also specify the standing charges which he wishes to insure.

The basis on which the amount of the loss is calculated is usually "turnover," that is, money received or due on goods sold or work done. Each period for which a payment is to be made is compared with the corresponding period in the 12 months immediately before the fire (an adjustment, if necessary, being made for unusual circumstances, such as strikes, effecting the business during the time) and the shortage in turnover found. The sum insured is then compared with the turnover for the named period up to the fire and a percentage obtained, which must not, however, exceed the proportion of profits and standing charges to turnover for the last complete financial year. The lower of these two percentages of the shortage in turnover is the sum recoverable for the period. Some modification of this method must, however, be adopted to obtain an equitable result for an expanding business. The policy conditions stipulate that the business property must be insured against fire and that liability under the fire policy must be admitted before a claim is paid on the profits policy. No payment will be made if the business is liquidated or permanently discontinued after the fire. The assessment of losses in the manner described sometimes involves considerable difficulty and it is usually arranged that the services of a qualified accountant be employed.

BY COURTESY OF THE METROPOLITAN MUSEUM, N.Y. CITY
ENGLISH FIREPLACE SHOVEL AND TONGS OF THE 19TH CENTURY

FIRE-IRONS, the implements for tending a fire. Usually they consist of poker, tongs and shovel, and they are most frequently of iron, steel, or brass, or partly of one and partly of another. The more elegant brass examples of the early part of the 19th century are much sought after for use with the brass fenders of that date. They were sometimes hung from an ornamental brass stand. The fire-irons of our own times are smaller in size and lighter in make than those of the best period. A typical example of the fireplace furnishings of the 18th and 19th centuries is shown in the accompanying illustration. In addition to the above, the bellows, the various cooking utensils, the hearth broom, etc., as well as the containers and receptacles about the mantel, make an interesting collection of fireplace furnishings.

FIRELESS COOKER. A device, smaller than the brick oven (*q.v.*), for cooking by conserved heat, and consisting of a food container packed by means of insulating material in an air-tight compartment. The food in the container is first brought to a good heat over a fire and then placed in the cooker, which is tightly closed. Baking is done by placing the food in a wire basket, under and over which are placed "stones" heated over a fire. The first fireless cookers used hay as the insulating material—the Norwegian haybox, and the homemade cookers in the United States generally have excelsior (wood-shavings) or crushed newspaper as packing. Manufactured fireless cookers, however, are now in general use; the insulating material is of various kinds, and these cookers are more sanitary than the homemade, as the lining—usually of aluminium—is nowhere penetrable by liquid or food. Gas and electric ranges are now made with insulated ovens, which act as fireless cookers. Any fireless cooker conserves cold as well as heat, and may be used for "still frozen" dishes. The advantages of the fireless cooker are: (1) economy of fuel, (2) economy of time and labour, since the food needs no attention while cooking, (3) economy of utensils, (4) absence of heat and odours.

FIRENZUOLA, AGNOLO (1493–c. 1545), Italian poet and litterateur, was born at Florence on Sept. 28, 1493. He studied law at Siena and afterwards at Perugia, where he became the associate of the notorious Pietro Aretino, and copied his licentious way of living, though he is stated to have worn the monastic habit for a time. Firenzuola practised for some time as an advocate at Rome, and eventually settled at Prato as abbot of San Salvatore. His writings are of great importance in the history of Italian literature because they are written in Tuscan just as the literary style began to emerge from popular speech. He wrote *Discorsi degli animali*, imitations of Oriental and Aesopian fables; *Dialogo delle bellezze donne* (Eng. trs. 1892); *Ragionamenti amorosi*, a series of short tales in the manner of Boccaccio (Eng. trs. 1889); *Discacciamento delle nuove lettere*, a controversial piece against Trissino's proposal to introduce new letters into the Italian alphabet; a free version of the popular *Golden Ass* of Apuleius; and two comedies, *I Lucidi*, an imitation of the *Menaechmi* of Plautus, and *La Trinzia*, which in some points resembles the *Calandria* of Cardinal Bibbiena. His poems are chiefly

satirical and burlesque.

The best edition of his collected works is that by Bianchi (Florence, 1848).

FIRE PREVENTION AND EXTINCTION. Every fire involves a permanent and absolute loss of national capital, but the loss is usually so well distributed by the existing system of insurance that its incidence is not often seriously felt. Fire losses are in reality borne by the community, insurance offices being merely the medium by which the loss is distributed. The enormous annual fire wastage passes unnoticed and it is only when a conflagration occurs by which the accumulation of years of wealth of property is swept away in a few hours that the imagination is moved.

The following is a list of notable fires:

GREAT BRITAIN AND IRELAND

Year A.D.

798. London, nearly destroyed.
 982. " greater part of the city burned.
 1212. " greater part of the city burned.
 1666. " "The Great Fire," Sept. 2nd.
 It began in a wooden house in Pudding lane, and burned for three days, consuming the buildings on 436 acres, 400 streets, lanes, etc., 13,200 houses, with St. Paul's church, 86 parish churches, 6 chapels, the guild-hall, the royal exchange, the custom-house, many hospitals and libraries, 52 companies' halls, and a vast number of other stately edifices, together with three of the city gates, four stone bridges, and the prisons of Newgate, the Fleet, and the Poultry and Wood street Compters. The fire swept from the Tower to Temple church, and from the north-east gate to Holborn bridge. Six persons were killed. The total loss of property was estimated at the time to be £10,730,500.
 1834. London, Houses of Parliament burned.
 1137. York, totally destroyed.
 1292. Carlisle, destroyed.
 1544. Leith, burned.
 1700. Edinburgh, "The Great Fire."
 1612. Cork, greater part burned and again in 1622.
 1614. Stratford-on-Avon, burned.
 1675. Northampton, almost totally destroyed.
 1694. Warwick, more than half burned; rebuilt by national contribution.
 1893. Liverpool, Canada dock, timber yard. Loss, £1,000,000.
 1920. " damage by Sinn Feiners. Loss, £1,000,000.
 1921. London, Hackney Wick, timber yard. Loss £500,000.
 1922. West Hartlepool, docks, timber storage ground. Loss, £600,000.
 1923. London, Victoria dock, tobacco. Loss, £1,000,000.
 1924. London, Butlers' wharf. Loss, £350,000.

FRANCE

59. Lyons (Lugdunum) burned to ashes. Nero made an offer to rebuild the city.
 1118. Nantes, greater part of the city destroyed.
 1862. Marseilles, destructive fire.
 1871. Paris. Suppression of the Commune (*q.v.*). Property destroyed, £32,000,000.
 1922. Paris, "Printemps" store. Loss, £750,000.

CENTRAL AND SOUTHERN EUROPE

64. Rome burned during 8 days. Ten of the 14 wards of the city were destroyed.
 1106. Venice, greater part of the city was burned.
 1577. Venice, fire at the arsenal, greater part of the city ruined by an explosion.
 1379. Memel was in large part destroyed, and again in 1457, 1540, 1678, 1854.
 1491. Dresden was destroyed.
 1758. Pirna was burned by Prussians. 260 houses destroyed.
 1811. Forest fires in Tyrol destroyed 64 villages and hamlets.
 1842. Hamburg. A fire raged for 100 hours. May 5-7. During the fire the city was in a state of anarchy. 4,219 buildings including 2,000 dwellings were destroyed. One-fifth of the population was made homeless, and 100 persons lost their lives. The total loss amounted to £7,000,000. After the fire, contributions of varying amounts from all Germany were received to assist in the rebuilding of the devastated areas of the city.
 1883. Vienna. Loss, £1,000,000.
 1901. Antwerp, L'Entrepôt Royal. Loss, £1,000,000.
 1910. Brussels, Brussels Exhibition. Loss, £1,750,000.
 1922. Geneva, Northern railway station destroyed. Loss, £400,000.
 1926. Bacau (Rumania). Loss, £1,000,000.

NORTHERN EUROPE

1624. Oslo, nearly destroyed, Christiania was built on the site.
 1728. Copenhagen, nearly destroyed; 1,650 houses burned, 77 streets.
 1794. Copenhagen, royal palace with contents burned.
 1751. Stockholm, 1,000 houses destroyed.
 1790. Carlsrona, 1,087 houses, churches, warehouses, etc., destroyed.
 1858. Christiania. Loss estimated at £250,000.
 1865. Carlstadt (Sweden), everything burned except the bishop's residence, hospital and jail. Ten lives lost.

RUSSIA AND SIBERIA

1862. St. Petersburg, great fire. Loss, £1,000,000.
 1752. Moscow, 18,000 houses burned.
 1812. Moscow, the Russians fired the city on Sept. 14 to drive out the army of Napoleon. The fire continued five days. Nine-tenths of the city was destroyed. Number of houses burned 30,800. Loss, £30,000,000.
 1786. Tobolsk, nearly destroyed.
 1812. Riga, partly destroyed.
 1850. Cracow, large part of the town burned.
 1879. Irkutsk. Loss, £4,500,000.

TURKEY AND THE NEAR EAST

1750. Constantinople. In Jan. 10,000 houses burned; in April property destroyed estimated from £1,000,000 to £3,000,000. Later in the year 10,000 houses were destroyed.
 1756. Constantinople, 15,000 houses and 100 people destroyed. During the years 1761, 1765 and 1767 great havoc was made by fire.
 1782. Constantinople, Aug. 12 a fire burned three days: 10,000 houses, 50 mosques and 100 corn mills destroyed; 100 lives lost. In Feb. 600 houses burned; in June 7,000 more.
 1784. Constantinople, Aug. 5 a fire burned for 26 hours and destroyed 10,000 houses, most of which had been rebuilt since the fires of 1782. In the same year, March 13, a fire in the suburb of Pera destroyed two-thirds of that quarter. Loss estimated at 2,000,000 florins.
 1870. Constantinople, June 5, the suburb of Pera, occupied by the foreign population and native Christians, was swept by a fire which destroyed over 7,000 buildings, many of them among the best in the city, including the residence of the foreign legations. Loss estimated at nearly £5,000,000.
 1871-1926. Constantinople. Fires of greater or less severity have continued to be of almost annual occurrence, particularly in Stamboul, where hundreds of acres have been swept clear time after time, large areas never being rebuilt and becoming permanently deserted. Constructed mostly of timber, whole quarters are always at the mercy of a minor accident which elsewhere would be quenched at the outset.
 1772. Smyrna, 3,000 dwellings burned. 3,000 to 4,000 shops, etc., consumed. Loss, £4,000,000.
 1923. Smyrna, conflagration attributed to the war between the Turkish and Greek armies. Loss, £20,000,000.

INDIA, CHINA AND THE FAR EAST

1799. Manila, vast storehouses were burned.
 1803. Bombay, loss by fire of £600,000.
 1822. Canton (China), was nearly destroyed by fire.
 1866. Yokohama (Japan), two-thirds of the native town and one-sixth of the foreign settlement destroyed.
 1919. Yokohama. Loss, £5,000,000.
 1923. Tokio and Yokohama. As a result of an earthquake about seven-tenths of the city of Tokio and most of the city of Yokohama were destroyed by fire. Loss estimated at £200,000,000.
 1924. Canton, conflagration as a result of insurrection. Loss, £4,000,000.
 1925. Kumagaya (Japan), central portion of town burned out. Loss unknown.
 1927. Kanazawa (Japan). Loss, £400,000.

AUSTRALIA AND NEW ZEALAND

1888. Brisbane. Loss, £400,000.
 1897. Melbourne, Flinders lane. Loss, £1,000,000.
 1901. Sydney, Anthony Hordern & Sons. Loss, £400,000.
 1909. Christchurch (New Zealand). Loss, £300,000.
 1921. Kirribilli, about 32,000 bales of wool burned. Loss, £750,000.
 1925. Melbourne, Lincoln Knitting Mills. Loss, £1,000,000.
 1926. Adelaide, Colonial Sugar Refining Company. Loss, £700,000.

SOUTH AFRICA

1902. Cape Town, City chambers. Loss, £250,000.

UNITED STATES OF AMERICA

1911. Albany, State Capitol building. Loss, \$5,500,000.
 1908. Atlanta (Georgia). Loss, \$11,500,000.
 1917. " " Loss, \$5,000,000.

1922. Astoria (Oregon), business quarter destroyed. Loss, \$15,000,000.
1904. Baltimore (Maryland), 80 city blocks involved. Loss, \$50,000,000.
1922. Baltimore, grain elevators. Loss, \$5,000,000.
1923. Berkeley (California), forest fire which destroyed 600 buildings. Loss, \$12,500,000.
1760. Boston, a fire caused a loss estimated at \$500,000.
1872. Boston, Great Fire, Nov. 9-10. By this fire the richest quarter of Boston was destroyed. The fire commenced at the corner of Summer and Kingston streets. The area burned over was 65 acres. 776 buildings, comprising the largest granite and brick warehouses of the city, filled with merchandise, were burned. The loss was about \$75,000,000. Before the end of the year 1876 the burned district had been rebuilt more substantially than ever.
1880. Boston. Loss, \$10,000,000.
1926. Brea (California), oil reservoirs. Loss, \$8,500,000.
1871. Chicago. One of the greatest fires of modern times. It began in a barn on the night of Oct. 8 and raged until the 10th. The area burned over was 2,124 acres, or 3½ sq.m. of the very heart of the city. 250 lives were lost, 98,500 persons were made homeless, and 17,430 buildings were consumed. The buildings were one-third in number and one-half in value of the buildings of the city. Before the end of 1875 the whole burned district had been rebuilt. The loss was estimated at \$195,000,000.
1874. Chicago, new post office, etc. Loss, \$5,000,000.
1922. Chicago, office premises. Loss, \$8,000,000.
1900. Hoboken (New Jersey), dock fire. Loss, \$5,000,000.
1901. Jacksonville (Florida). Loss, \$10,000,000.
1916. Jersey city, warehouses and steamers. Loss, \$20,000,000.
1917. Kingsland (New Jersey), munition factory. Loss, \$12,000,000.
1882. Leadville (Colorado). Loss, \$10,000,000.
1918. Minnesota, forest fire—Colquet and 25 other towns involved. Loss, \$25,000,000.
1922. New Orleans, warehouses. Loss, \$5,000,000.
1835. New York. The great fire of New York began in Merchant street, Dec. 16, and burned 530 buildings in the business part of the city. 1,000 mercantile firms lost their places of business. The area burned over was 52 acres. The loss was \$15,000,000.
1845. New York. A fire in the business part of the city, July 20, destroyed 300 buildings. The loss was \$7,500,000. 35 persons were killed.
1916. Paris (Texas). Loss, \$11,000,000.
1850. Philadelphia. 400 buildings burned July 9. 30 lives lost. Loss, \$1,000,000.
1845. Pittsburgh. A large part of the city burned April 11. 20 squares, 1,100 buildings destroyed. Loss, \$10,000,000.
1866. Portland (Me.). Great fire on July 4. One-half of the city was burned; 200 acres were ravaged; 50 buildings were blown up to stop the progress of the fire. Loss, \$10,000,000 to \$11,250,000.
1851. San Francisco. On May 4-5 a fire destroyed 2,500 buildings. A number of lives lost. More than three-fourths of the city destroyed. Loss, upwards of \$10,000,000.
1906. San Francisco. This calamity, which will count among the worst ever experienced by the cities of America, started at a quarter past five in the morning, a shock of earthquake swaying buildings throughout the city. Hotels, theatres, wholesale warehouses, factories and stores toppled over, caught fire, and were demolished. The city hall, erected at a cost of \$4,000,000, containing a free library of 85,000 volumes, was completely wrecked. The Grand Opera House, Majestic, Columbia and Orpheum theatres fell to pieces, each being consumed by the flames. The Palace hotel, an enormous building constructed to resist earthquakes, survived the earlier shocks, only to fall a prey to the conflagration. The Valencia hotel fell over, burying 70 or 80 people beneath its ruins. Total loss of life about 1,000. Area of fire seven square miles. Total damage, about \$250,000,000.
1926. San Luis Obispo (California) Union Oil Company's property. Loss, \$8,750,000.
1849. St. Louis. 23 steamboats at the wharves and the whole or part of 15 blocks of the city burned, May 17. Loss, \$3,000,000.
1851. St. Louis. More than three-quarters of the city was burned, May 4: 2,500 buildings. Loss, \$11,000,000.
1851. St. Louis. 500 buildings burned. Loss, \$3,000,000.
1862. Troy (New York), was nearly destroyed by fire.
1875. Virginia City (Nevada). Loss, \$7,500,000.
1851. Washington. Part of the Capitol and the whole of the Congressional library were burned.

WEST INDIES

1873. Havana (Cuba). Loss, £600,000.
1882. Kingston (Jamaica). Loss, £6,000,000.

1927. St. Lucia, 17 blocks of business premises burned at Port Castries. Loss, £300,000.

CANADA AND NEWFOUNDLAND

1825. New Brunswick. A tract of 4,000,000 acres, more than 100 miles in length, was burned over; it included many towns. 160 persons killed and 875 head of cattle. 590 buildings burned. Towns of Newcastle, Chatham and Douglas destroyed. Loss about \$300,000.
1923. New Brunswick, forest fires. Loss, \$20,000,000.
1837. St. John (New Brunswick). 115 houses burned, Jan. 13, and nearly all the business part of the city. Loss, \$5,000,000.
1877. St. John (New Brunswick). This fire extended over an area of 600 acres. Loss, \$15,000,000.
1892. St. John's (Newfoundland). Loss, \$15,000,000.
1900. Ottawa (Hull) (Ontario). Loss, \$7,500,000.
1904. Toronto (Ontario); general conflagration involving 120 mercantile buildings. Loss, \$7,500,000.
1922. Ontario, forest fires. Loss, \$15,000,000.

A conflagration is but the development of a small fire, and a study of the great fires in history shows that certain conditions, or a combination of circumstances, have on each occasion permitted the individual fire to spread. A convulsion of nature, insurrection, or interference with the civic authorities, a strong wind, scarcity of water, lack of fire-fighting appliances, defective construction of buildings, all contribute to the disaster. An earthquake may destroy the water supply and leave a city to the mercy of the flames. This happened in the great conflagration in San Francisco in 1906, while defective construction fed the fires which wiped out Yokohama and large districts of Tokio following the terrible earthquake in September 1923.

Where timber buildings predominate, high winds are dreaded by firemen almost as much as a scarcity of water, but, even in the absence of wind at the outbreak a conflagration creates its own wind as it gains in volume, which adds to the difficulty of confining the disaster.

Discipline and good housekeeping in shop and factory reduce the danger of fire, and every appliance devised whereby fires are confined to the seat of outbreak is a step forward in the progress of fire protection.

"Fire protection is a combination of fire prevention, fire combating and fire research."

Fire Prevention.—By the common law of England every householder was bound so to keep his fire as to prevent it from causing injury to others. A statute was passed in the reign of Queen Anne which enacted that after a day named no action should be maintained against any person in whose house any fire should *accidentally* begin, and these provisions were re-enacted under the Fire Prevention (Metropolis) Act 1774, which is general in its application and not confined to the Metropolis. The responsibility for damage by fire is particularly expressed in the law of France under the Code Napoleon. This code, which took effect in 1804, was adopted in many lands conquered by Napoleon and it has also had great influence on the legislation of countries outside Europe, particularly in Central and South America. The following are the special provisions:—

Recours des Voisins (neighbours' risk).—The owner of property or goods which are burned may become responsible for any damage sustained by his neighbours through the burning. This is called "recourse by the neighbours." In order to obtain the benefit of this recourse the neighbour must prove that his loss was caused by the fault of him on whose premises the fire started. It should, perhaps, be especially emphasized that the "onus probandi" rests on the neighbour and not on the owner himself.

Risque Locatif (tenants' risk).—A tenant is responsible for a fire unless he proves that it happened through unforeseen circumstances, by act of God, or through faulty construction of the premises, or that the fire had been communicated from a neighbouring house. If there are several tenants, all are responsible for the fire proportionately to the value of the part of the premises which they occupy except in the two following cases:

- where it is proved that the fire originated in the part occupied by one particular tenant, in which case he alone is held responsible.
- where it is proved by some of the tenants that the fire did not originate in the part occupied by them, in which case they free themselves from liability, which falls on the remaining tenants.

This is called the "tenant risk" and in virtue of the law the owner of the house has a right to sue the tenant of the house for payment of the damage which his house has sustained, and in order that he may recover the law only requires proof of the *damage*, without any reference to the *cause*.

Risque Locataires (landlords' risk). The law having put this burden on the tenant also contains some provisions for his protection:

The landlord of a building is responsible for the damage caused by this destruction when it happens in consequence of want of maintenance or by fault of its construction. The landlord is bound to guarantee the tenant for all the defects in the building which would prevent the use of it, even although the landlord may not have known of them at the time of the lease being made. If there result to the tenant any loss through these defects the landlord is bound to indemnify him. This provides for the recourse of the tenant against the landlord.

But quite apart from legal liability, it is the moral duty of every citizen to see that his building is erected or maintained in such a manner as to reduce the danger of fire and of every occupier to guard against such a danger and, in the event of an outbreak, to take every step possible to extinguish it and prevent it from spreading.

Town planning acts with their provisions for minimum widths of streets, fire prevention and building acts and municipal by-laws based on the practical experience and research of builders, engineers and fire experts have done something to reduce fire waste. Such enactments regulate the materials used in the construction, fix the dimensions and particularly the height of buildings, and control the conditions under which hazardous processes of manufacture may be carried on, but they are not of universal application. From a fire prevention point of view, the general acts are inadequate in their provisions and in some cases they are permissive only and not compulsory.

The origin of many fires may be traced to lack of attention to details of construction. Defective chimneys, want of care in the construction of hearths, and insecure stoves and boilers are common causes of fire, while open wells, hoists and stairways with timber linings and partitions cause it to spread rapidly.

Loss by fire can be reduced and the safety of a building favourably affected by the following:

No timber or other combustible material should be used in the external walls or windows; large areas should be avoided, by properly constructed division walls and cut offs carried well through the roof to a height regulated by the nature of the building; Mansard roofs or high-pitched roofs are a fruitful source of extra risk, both on account of the excessive amount of wood used in their construction and the steep angle at which they are built; the use of wood should be reduced to a minimum; all vertical openings (hoists, shafts, stairways, etc.) should be enclosed with fireproof materials—such openings are well known to be the most active factors in the rapid development of a fire; metal posts and girders must be insulated against severe heat; walls should not be lined with wood as the spread of a fire is accelerated by the air draughts which this mode of construction promotes and partitions should be made of non-inflammable materials; flues should only be used for the purpose for which they were designed and stoves and smoke pipes should be securely erected and free from contact with woodwork; windows should be of wired glass or protected by metal shutters where there is exposure to another building.

Every care should be taken to see that the lighting system is properly installed. Gas brackets should be securely fixed. A gas burner has been known to fire a ceiling 28 inches from it and light fabrics are frequently fired at a greater distance. Electricity, although apparently the safest method of lighting has from the mysterious and subtle nature of its working been found by experience to be dangerous when not properly installed. Even under the most approved methods, there is always the danger of short circuits, leaks and contacts, and numerous fires are due to these causes. Such installations should only be installed according to the rules of the institute of electrical engineers and they should be inspected at intervals by established and reputable firms of

electrical engineers.

Carelessness.—But the majority of fires are due to carelessness: a match carelessly thrown away or the cigarette end left in close proximity to combustible material. The "no smoking" sign in factory or warehouse is often ignored and the guilty individual fails to realize how his act is a menace to life and property.

In the report of the royal commission on fire brigades and fire prevention published in 1923, the commissioners say:

"We also observe that, in the report of the chief officer of the London fire brigade for 1921, 2,054 fires out of 5,281, or nearly 40% of the whole number, are attributed to carelessness. The factor of carelessness, it is safe to say, can never be wholly eliminated, but in view of the very serious loss of life and property due to fires which could have been avoided by the exercise of reasonable care, we would urge the importance, in the national interest, of efforts being made in all possible directions to inculcate a more general and better instructed regard to the consequences of carelessness and negligence in matter of fire prevention. In this country the annual average direct loss of property caused by fires, attributable to all causes, amounts to about £12,000,000 per annum. If it be assumed, as we think it safe to do, that of this a considerable proportion could have been avoided by the exercise of a proper care, it will be seen that there is a wide field for further warning and instruction."

In Great Britain it is difficult to interest public opinion in the subject of fire prevention. In the United States of America the tremendous annual fire wastage has roused the authorities to action, and in the press and in the school they are endeavouring to create a public sentiment against what has become a national disgrace.

The danger of arson is ever prevalent and bad trade is one of the chief factors which give rise to the temptation to turn an insurance policy into a source of gain. It is remarkable how, in all parts of the world, the curve of falling business is consistently offset by the curve of rising fire losses. From this it must not be taken that moral hazard is bad all over the world, but that bad trade reveals inherent weaknesses in a community which normal or good business leaves unsuspected. When trade is bad, carelessness, to give it no worse name, increases, and the tendency is to pare down expenses in every direction until, in some cases, the safety line is passed—and the fire which results will not be at all unwelcome to the owner who finds himself in financial difficulties.

On the outbreak of a fire it is, in the first instance, the duty of the person on whose property the fire takes place to take all reasonable steps to extinguish it or to prevent it from spreading. The two most important aids to fire suppression are early discovery of the outbreak and an immediate application of the means of putting it out. Automatic appliances are the best, as they fulfil both these requirements. Failing these, every building should be provided with some other ready means for dealing with an outbreak. A pail of water is the most primitive fire extinguisher known and is valuable if available during the first few minutes. For a chimney fire a few pounds of salt thrown in at the top is probably the best handy extinguisher. A pail of sand, dry earth, salt or even sawdust is also useful in extinguishing fires in inflammable liquids. If such fires are not too large they may often be smothered by covering with a rug or blanket, but water will spread such burning fluids rather than extinguish them.

A garden hose stored where handy for quick attachment to a service pipe is an excellent fire protective appliance.

Fire Extinguishing Appliances.—Chemical extinguishers, of which there are many satisfactory types on the market, are most effective in the early stages of a fire. Their cost is not excessive and their intelligent use is often more valuable than a fire brigade which must first be summoned and then perhaps travel half a mile or more to reach the scene.

They should be placed on different floors and be easily accessible. Such extinguishers should be recharged periodically because, if this is neglected, they may fail to act in an efficient manner when they are most needed.

If petrol or other inflammable liquids not easily extinguished by water are stored in the building, a foam type of chemical extinguisher should be provided and this type should be installed in every garage.

Automatic Fire Alarms.—There are several useful automatic fire alarms on the market, their purpose being to ring an alarm gong fixed outside the building or to convey a danger signal to a fire brigade station.

These alarms are brought into action whenever the temperature in the room is raised to a point well above what may be regarded as the highest natural temperature to be expected. The apparatus works by means of thermostats fixed at frequent and suitable points in the upper parts of all rooms, staircases, etc., where the heat rising from a small fire would concentrate causing expansion and electrical contact. Within a few seconds of an outbreak, alarm bells are set ringing and the position of the fire shown on an indicator board.

Automatic Sprinkler Installations.—The most effective system for automatic fire extinction and warning of fire is the sprinkler installation, which originated in America and was introduced into Great Britain about the year 1880. The invention has been successfully applied to almost every kind of building and has undoubtedly averted much destruction of property and considerably reduced the cost of fire insurance where it is installed; insurance companies always being willing to grant substantial premium rebates where efficient installations have been fitted.

The protected building is provided with a system of piping containing water under pressure and fixed near the ceiling of every room and into this piping the sprinkler heads are inserted at such intervals that every part of the area will be commanded and drenched. These sprinkler heads are constructed to open at a temperature of 155° F (=68° C) and when so open discharge water directly on to the fire within a few seconds of its outbreak. To the installation is attached an automatic alarm bell fitted outside the building which operates simultaneously with the sprinkler head, thus giving the alarm in the very act of operating. The existence of fire is notified and extinguishing operations commence, therefore, practically instantaneously, and as efficient means are provided for turning off the water supply as soon as the fire is extinguished, the water damage is a minimum.

The safety secured by such an equipment fully justifies the expenditure, while the premium rebates referred to above are usually sufficiently substantial to repay the cost of initial installation in the course of a very few years.

The fixtures can be so placed as not to interfere with decorations or be otherwise obtrusive, as can be seen when visiting most of the larger departmental stores in England or abroad. In the majority of cases it takes a practised eye to detect the presence of sprinkler heads.

An extension of the sprinkler system is used when a building is subject to the risk of fire spreading from adjacent premises. In such cases external drenchers are fitted to the exposed windows and provide a curtain of water, effectually preventing entry of sparks or flame and keeping air temperature below ignition point of any inflammable goods near the openings. (E. M. M.)

A special automatic fire extinguisher system, in use since 1917, is a method by which a sprinkler system (and also an alarm system, if desired) is actuated when a fire causes a predetermined rate of rise of temperature. This has been approved by underwriters as preaction and deluge sprinkler system. Rate of rise principle utilized by Lowe Release to close fire doors. (X.)

Fire Escapes.—The protection of life from fire is quite as important as the saving of property. Certain building acts provide for the maintenance of means of escape in case of fire by the owner of the building. Such regulations apply more particularly in connection with public buildings and the like. Under the Factory and Workshop Act in Britain similar provision is made for factories where any considerable numbers are employed. Each individual tenant or occupier of a building has, however, a duty to perform in making provision for the escape of those employed by him or under his care.

Fire brigades in large towns are usually provided with fire escape ladders, but these may not reach the scene in time to save the lives which may be in danger. In many buildings escape by a single stairway is sometimes impossible and at least one additional means of safe exit should be provided, particularly for

the upper storeys. The logical and natural solution of the problem is the introduction of an additional stairway, but, should this be impossible, a "chute" or rope ladder may save a tragedy.

The "chute" fire escape consists of a strong canvas bag fitted on a wrought iron frame specially made for each window. The rope ladder type is attached to a hook fixed in the wall and provides a ready means of quickly leaving a burning building. Another fire escape consists of a canvas seat, the lowering rope being attached to a hook and break-rod. The individual is strapped in securely and by this means persons can be lowered and hoisted as easily and readily as by an ordinary rope over a pulley. (See also FIRE ESCAPE.)

Fire Brigades.—The gradual evolution of the modern fire brigade with its appliances in the United Kingdom from the primitive "*Couvre Feu*" used in the reign of King Alfred would be a very long story. That on the Continent and other countries would be a very much longer one, for it is certain that organized brigades existed in civilized countries many centuries B.C., and they existed at a much later period with the Romans. With the decay of wealth they gradually fell into disuse, and one would suppose on the principle that there was not much to protect, and in the exact opposite direction they have risen again to their high state of efficiency proportionately to the wealth that they have to protect.

The organized fire brigades of most countries, therefore, follow very much in the same direction as that of Great Britain, proportionately to the wealth of such other countries. There is an international exchange of ideas, and very little distinction in the principles of all fire brigades in civilized countries. A short history, therefore, of the fire brigade of the greatest city in the world, namely London, will suffice to indicate the general trend of things in relation to fire brigades all over the world so far as the large towns are concerned.

The establishment of fire insurance companies in Great Britain naturally brought about the question of minimizing loss by fire by preventing its spread, and as the public authorities had been diffident in this connection the offices set about establishing brigades of their own. Probably the first insurance office to possess fire engines was the "Royal Exchange," and an announcement was made by them in 1722 that they had provided several engines with firemen and watermen and their implements for extinguishing fires. They were followed by many other offices who placed fire marks on the buildings they insured, and no doubt each particular brigade gave special attention to any premises insured in their own company. In 1833 the London fire engine establishment was formed by a combination of offices, this consisted of 76 officers and men who took upon themselves practically the fire protection of London. A year later the Houses of Parliament were destroyed by fire, and in 1861 the great fire in Tooley street occurred, when damage estimated at £1,200,000 was done. In the following year a parliamentary committee was formed "to enquire into the existing state of legislation, and of any existing arrangements for the protection of life and property against fires in the metropolis." The result of this enquiry was to show a total inadequacy of appliances should a great fire occur in the metropolis, and in 1865 the fire offices handed over to the metropolitan board of works the fire protection of London which for over 30 years they had carried on at their own cost.

Various statutes were subsequently passed by parliament, not only in relation to London but to other towns throughout the country, by which parliament recognized as a public duty the maintenance of a proper equipment to local authorities, the cost of which is to be borne from the rates. The Metropolitan Fire Brigade Act of 1865 provided for the handing over of the fire stations, engines and property of the London fire engine establishment, together with the force of firemen, to the board of works, and this formed the nucleus of the new metropolitan fire brigade. The insurance companies being relieved from the burden of the onus of extinguishing fire, not only handed over their freehold and leasehold properties and valuable appliances worth many thousands of pounds, but consented to an arrangement whereby they became liable to contribute to the upkeep of the brigade.

Every insurance company that insures the risk of fire on any property within the metropolitan area must pay annually the sum of £35 per million on the gross amount insured. At the date of the passing of this act contributions made by the insurance offices thereunder amounted to a sum of £10,000 per annum, and some idea may be gleaned of the wealth in the metropolitan area from the fact that this contribution had in 1925 amounted to no less a sum than £73,159 per annum, being at the same rate of £35 per million on sums assured of no less than £2,090,280,942. This latter sum is double the amount of the gross sum assured in 1904.

The staff of the London fire brigade at Dec. 31, 1926, consisted of one chief officer, two divisional officers, two assistant divisional officers, one senior superintendent, seven superintendents, nine district officers, 74 station officers, 195 sub-officers, 1,620 firemen and probationary firemen and 13 pilots.

The stations and chief appliances were as follows: 62 land fire stations, three floating river stations, one river repairing depot, 87 petrol motor fire engines, 69 petrol motor escape vans, five electrically driven motor escape vans, two electrically driven motor ladders, six petrol-electric motor ladders, three petrol motor ladders, one petrol-electric emergency tender, one petrol-electric foam tender, one petrol emergency tender, five petrol motor tenders, 62 miles of hose (including first-aid hose), two steam fire floats, three motor fire floats, four store barges, 114 fire escapes, one long fire ladder, 55 smoke helmets, three cellar pipes, 399 hook ladders, 293 hook belts, 1,654 street fire-alarm posts, 108 telephone lines from fire stations to other fire stations, etc., 43 telephone lines between telephone exchanges and fire stations, 362 telephone lines to public and other buildings.

During 1926 there were 4,919 fires, of which 21, or .43%, were serious, 4,111, or 83.57%, were slight, and 787, or 16.0%, were chimney fires; 7,433 calls were received, of which 2,514 were false alarms. Of the false alarms 728 were malicious, 1,080 were due to defective electric circuits, one to automatic alarm and 705 to other causes. The number of serious and slight fires compared with 1925 shows a decrease of 43. The probable causes were: Structural defects, 228; lighting (electricity), 259; lighting (gas), 104; lighting (oil), 222; heating, 696; in the exercise of business or industry, 1,121; carelessness, 1,376; suspicious, 36; unknown, 90.

No less than 265 officers and men were injured in the execution of their duty.

The quantity of water used for extinguishing fires was approximately 14,202,442 gallons or 63,403 tons.

In brigades in the United Kingdom apart from London, conditions and regulations vary very considerably, and the report of the royal commission on fire brigades and fire prevention, 1923, states that "the existing provisions on the subject, apart from any question of their being inadequate or ill-adapted to modern conditions, are somewhat fragmentary and scattered over a number of statutes, and it would be a great advantage if, when the law is amended to meet its present defects, the opportunity were taken at the same time to consolidate the whole of the provisions relating to equipment, maintenance and operations of fire brigades in one comprehensive measure."

They find that the maintenance of the fire service in all cases where authorized is a matter for the discretion of the authorities, and the extent to which that discretion has been exercised varies considerably.

Apparently there are some 1,500 fire brigades of every description in England and Wales.

Considerable improvement in the standard of fire protection generally has taken place throughout Great Britain in the last two decades, and broadly speaking the large cities and boroughs are fairly well protected as regards their own fire risks. In the smaller boroughs and urban districts the conditions vary very widely. Some of these authorities have built up an efficient organization, whilst others seem to have regarded the subject of fire protection as of minor importance. In the rural areas generally, probably owing to defective legislation, the fire protection provided is on the whole quite inadequate for the needs of the

districts.

The report goes on to say: "In the industrial areas round Birmingham and in that portion of England which lies between Preston, Lancaster and Liverpool on the west, and Hull and Grimsby on the east there are many towns well provided with appliances, and probably, if all the fire brigade resources of this area were available for service independently of the local authorities areas to which, for the most part, their operations are confined, reasonably adequate provision would be made for most areas in this part of the country. On the other hand, taking a general view of the counties of Lincoln, Norfolk, Suffolk and Essex, we find a section of the country in which, if we apply the test of motor appliances, there are conspicuous blanks or deficiencies in equipment."

With regard to the protection of Wales a rather pessimistic view is taken. The county of Glamorgan, which embraces more than one-half of the population of the principality, appears to be the only bright spot. To quote the report: "In fact, in the whole of the principality, outside Glamorgan, only five motor pumps are mentioned in the returns."

So far as Scotland is concerned, "it would appear that the largest centres of population, such as Glasgow, Edinburgh, Dundee and Aberdeen are well protected against their own fire risks and that some effort has been made to assist in the protection of neighbouring areas. The counties of Lanark and Renfrew, which are in a special position as being protected by brigades organized on a county basis, may also be considered as favourably situated as regards their arrangements for fire defence. There are in other parts of Scotland some few burghs with brigades of moderate size, mostly on a retained footing, equipped with mobile appliances, which adequately serve for the protection of the township itself and afford to a greater or less degree a measure of protection for the surrounding districts, though in Scotland, as in England, the possibilities of co-operation for this purpose do not appear to have received the attention the matter deserves. Perhaps, however, the most striking feature of the distribution of fire brigades under the present organization is the wide extent of the areas without any mobile fire equipment of any kind. This, however, is in a large measure unavoidable, on account of the nature of the country, the difficulties of communication, scanty water supplies and the very limited number of centres where there is sufficient aggregate fire risk to justify the maintenance of any costly fire brigade organization. In the Highlands, particularly, there are great stretches of mountain, moor and forest, where destructive fires from time to time occur, but against which it seems impracticable to devise any systematic protection on an economic basis.

The advent of the motor pump has done much to facilitate the solution of the problem of efficient protection of the country as a whole; in particular it has enabled an efficient brigade in any given centre to protect a much wider area than was formerly possible with horse appliances, and has introduced entirely new possibilities in the direction of the rapid concentration of brigades in the event of any fire brigade finding itself unable to cope with an outbreak, or series of outbreaks, within its district. A brigade thus equipped can now provide normal protection over a radius up to, say, eight miles, including for example, a town of moderate size and surrounding rural area, more effectively than a brigade equipped only with horse appliances could have protected an area of half that radius.

There is no doubt that public opinion is moving in the direction of compulsory fire protection, to be controlled by the borough and urban and rural councils, with the co-ordinate authority of the county councils. The effect of this would be that the cost of the up-keep of brigades would in all cases be made payable out of the rates, so that insured and uninsured persons would be able to contribute alike, not only for the protection from fire, but against loss of life.

The following is a table of local authorities in Great Britain showing their statutory powers for the provision and maintenance of fire brigades, and indicating recovery of charges for services rendered at fires:—

BY COURTESY OF (1) AMERICAN LA FRANCE AND FOAMITE CORPORATION, (2) THE MAXIM MOTOR COMPANY, (3, 5) LEYLAND MOTORS, LTD.; PHOTOGRAPH, (4) TOPICAL PRESS AGENCY

MODERN APPARATUS FOR FIRE CONTROL AND PROTECTION

1. Triple combination pumping, chemical and hose motor car, equipped with 40 gal. chemical tank and 1,200 ft. hose. The rotary gear fire pump, shown beneath seat of car, is capable of delivering 1,000 gals. of chemical per minute at 120 lb. pumping pressure; hose connections at right
2. Service truck carrying extension ladders and chemical tanks. Hose in basket behind seat is used for extinguishing localized blazes with chemical stored in tanks beneath the ladders
3. English type pump and hose car with portable extension ladder, serving same purpose as those in figs. 1 and 2. The large wheels raised from ground at end of the car are used in moving the detachable ladder to any location
4. Fireman wearing gas mask for protection against smoke
5. Portable fire pump mounted on motorcycle chassis, for extinguishing small fires. Apparatus includes chemical tank and pump in rear of car, with four lengths of hose

Local authority	Statutory powers	Right to charge in district	Statutory liability for outside district

Boroughs (a few)	Special Town Improvement (Ireland) Act 1854	Special None	Special Owner of premises
Boroughs and Towns			

Note.—A rural district council can obtain, on application to the local government board, the powers of an urban authority under section 276 of the Public Health Act. In such a case their powers for fire protection would be under the Town Police Clauses Act.

The fire brigade committee of 1900 suggested that insurance companies should pay for brigade services rendered at fires but the commissioners in the report of 1923 came to the conclusion that "there appears to be no more reason for the fire department of an insurance company to subsidize fire brigades, than for the marine department to subsidize lighthouses, or the burglary department to subsidize the police."

In 1923 a scale of charges for Great Britain was drawn up by the National Fire Brigades Association which is now being adopted increasingly by brigades—it is in the next column.

1.—The scale of charges given covers wear, tear, fuel, cleaning and all other normal expenses incidental to the use of appliances or sustenance allowances for men and all other out-of-pocket expenses.

2.—The turn-out fee in every case is only chargeable if the appliance or appliances and their crews actually leave the station. If the call should be cancelled before the departure of the appliance, the charge will be the same as if for standing by at a fire for a period of one hour or less. The fees for stand-by at station or turn-out shall be limited to 1 officer and 12 men. The turning-out fee includes the time occupied in travelling to and from the fire.

3.—The brigade shall be entitled to the mileage charge for motor appliances on the total distance covered to and from the fire or other place to which the appliance is ordered. The charge shall be additional to the charge for turning out, and in the case of a steamer or manual the charge shall be the actual cost of horse hire.

4.—No charge is payable for the appliances if such are provided and maintained by the Local authority when attending fires in the local area, and in certain instances, where a local author-

ity enters into an agreement with a neighbouring authority which may contribute a subsidy or grant in aid towards the maintenance of the fire brigade, the charges to be made shall be in accordance with the terms of the joint agreement.

Water Supply at Fires.—The supply of water for extinguishing fires has, of course, a very large bearing on the efficiency or otherwise of the brigade. So far as England, Wales and Ireland are concerned urban authorities are compelled by statute to secure an adequate supply of water for extinguishing or preventing the spread of fire, and shall cause fire plugs and all necessary works, machinery and assistance for securing a sufficient supply of water in the case of fire.

Water companies cannot be compelled to increase the pressure other than that necessary for supplying water for domestic purposes, but where the fire service and water supply are both in the hands of the local authorities the pressure of water is usually adjusted to the circumstances of the case.

Without the consent of the owner a fire brigade cannot take water from a stream, pond or other private source for the purpose of extinguishing a fire, and the owner can either withhold his consent or make a charge for the water supplied.

In rural districts the water supply is a great difficulty, and so far nothing has been done to make it compulsory for an adequate supply of water to be maintained for extinguishing fires.

The march of modern science, while assisting the fire fighter by the provision of more efficient apparatus, is ever creating new problems. The motor car, which enables the brigade to reach the fire in a fraction of the time taken by horse-drawn vehicles, has, by its very existence, made petrol a commodity of almost universal use whose storage and manipulation have created special problems which still await satisfactory solution. It is a platitude

Appliances	For turning out	For run out and back per mile	For appliances or men at fire (standing by)	For engine while pumping
			Per hour or part thereof	
	£ s. d.	£ s. d.	£ s. d.	£ s. d.
Motor pump:				
300 gals. per minute or over	2 10 0	7 6	1 1 0	2 2 0
Under 300 gals. per minute	1 10 0	5 0	1 1 0	1 10 0
Fire float:				
1,500 gals. per minute or over	5 0 0	10 0	2 2 0	3 3 0
Under 1,500 gals. per minute	3 0 0	7 6	1 1 0	2 2 0
Motor-hauled steamer or petrol-driven steamer or trailer pump including hauling same	2 0 0	4 0	1 1 0	1 10 0
Steamer on railway truck	1 10 0	4 0	15 0	1 1 0
*Horsed steamer	1 5 0	..	15 0	1 1 0
*Manual	15 0	..	5 0	10 0
Motor escape	1 5 0	4 0	1 1 0	..
Motor lorry	1 0 0	2 6	5 0	..
Motor tender	1 5 0	4 0	1 1 0	..
Motor car not included above	7 6	1 6	3 6	..
			Up to first 5 hours	After 5 hours
Officer in charge of brigade at fire	10 0	..	per hr. 10/	per hr. 7/6
Fireman (each) in motor or steamer brigades	5 0	..	3/6	2/6
Fireman manual and other brigades	5 0	..	2/6	1/6

Any additional assistance or damage to apparatus by or arising from the direct result of the fire—the actual cost.

*Horse-hire additional.

to say that "plus ça change, plus c'est la même chose." but it seems to be certain that whatever advances the future may hold, the risk of fire will be always with us. (See also SALVAGE CORPS.) (E. M. M.)

NORTH AMERICA

The excessive fire waste of the United States and Canada is generally credited to the lavish supplies of building lumber available in North America, which have made it appear more economical to use wood in building construction even at the cost of frequent rebuilding than to use fire-resisting materials. The uncertain stability of town sites in the pioneering days was also a factor in retarding the erection of more permanent buildings. During the past quarter century, however, the cities of the United States and Canada have been largely rebuilt with a liberal use of fire-resisting materials and considerable thought to their protection, both within and without, against fire attack. During this period there has also been general municipal improvement in certain items, such as water supplies for fire extinguishment, the housing of fire alarm headquarters in isolated fire-resisting buildings and the standardization of hose coupling and hydrant fittings to permit outside fire departments to operate effectively when called upon for help in fighting conflagrations.

North American Fire Losses.—For the past decade the United States has shown a steady increase in fire losses with the exception of the year 1919. The total and per capita fire losses for this period are as follows:

Fire Losses in the United States
(Reports of National Board of Fire Underwriters)

Year	Property Loss	Per Capita	Year	Property Loss	Per Capita
1917 . .	\$289,535,050	\$2.79	1922 . .	\$506,541,001	\$4.63
1918 . .	353,878,876	3.36	1923 . .	535,372,782	4.84
1919 . .	320,540,399	2.99	1924 . .	549,062,124	4.90
1920 . .	447,886,677	4.23	1925 . .	559,418,184	4.85
1921 . .	495,406,012	4.47	1926 . .	560,548,624	4.79

Canada shows in contrast to the United States a decline in fire waste for the last four years of this decade as follows:

Fire Losses in Canada
(Reports of Dominion Fire Prevention Association)

Year	Property Loss	Per Capita	Year	Property Loss	Per Capita
1917 . .	\$26,298,400	\$3.32	1922 . .	\$54,390,000	\$6.11
1918 . .	33,870,000	4.12	1923 . .	48,282,000	5.36
1919 . .	25,216,300	3.00	1924 . .	45,906,500	4.99
1920 . .	28,081,200	3.27	1925 . .	40,729,724	4.35
1921 . .	45,015,900	5.22	1926 . .	38,395,096	4.15

Fire loss statistics, while not conclusive if taken for a single year are, however, valuable for comparison if taken over several years. A bad record for a single year may be the result of a single large fire. A continued high-burning record over several years is, however, an almost certain indication of the true conditions. Additional statistics compiled by the Dominion Fire Prevention Association are interesting as indicating the actual cost of fires to the Dominion by inclusion of other factors.

The following table shows the total cost of fire increased about 2½%, despite the 30% decrease in the actual fire losses. While the fire losses have been decreasing, the savings on this account have been balanced by the progressive increase in insurance premiums in excess of losses paid, and by somewhat increased expenditures for public and private fire protection.

Methods of Fire Prevention and Protection.—The principal causes of fires in buildings and stock are defective chimneys, accumulations of rubbish, carelessness in handling fire and flammable materials, defects in electric, gas and oil installations, and exposure, that is, ignition from fires in adjacent property. The use of wooden shingles on roofs and, in mercantile districts, wooden window trim in otherwise fire-resisting buildings facilitates the spread of flames.

In order to educate the public in fire safety its prevention is taught in the schools of many of the States and Canadian provinces, and a "fire prevention week" has been instituted in the United States and Canada to call attention to this form of preventable waste. There is no doubt that the American mind is better informed on this subject than ever before. The fact that the aggregate of fire losses has steadily increased during recent years of active public education is due partly to increased property values, but principally to the fact that the popular and engineering knowledge now available has not yet been generally applied to the problem. While the impoverishing effect of the fire waste is national, every fire is itself local, and until in every community the impulse and the machinery exist to attack local fire hazards, public education is only of potential value.

National Fire Protection Association.—Among the agencies promoting fire prevention in North America is the National Fire Protection Association, which formulates regulations governing special hazards such as gases, oils and electricity and for the required performance of automatic sprinklers, fire doors, extinguishers and other fire appliances. Since 1924 this association has maintained a field-engineering service to study conditions in cities having especially unfavourable fire-loss records and to create and stimulate local agencies for their improvement. Over one hundred cities have been visited since the inauguration of this project and improvements initiated. In a number of these cities marked reductions in fire losses have been shown in official reports as the direct result of an awakened civic consciousness, as is shown in the accompanying table:

City	Per capita fire loss			
	1923	1924	1925	1926
	\$	\$	\$	\$
Grand Rapids, Mich.	8.03	6.90	4.98	1.90
Norfolk, Va.	4.91	3.04	2.52	1.79
Concord, N.H.	11.14	4.91	4.90	4.17
Utica, N.Y.	5.01	3.00	3.01	1.94
Indianapolis, Ind.	4.23	3.47	3.38	1.82
Springfield, Mass.	6.14	2.82	2.76	3.10
Providence, R.I.	7.21	4.29	2.28	3.78
Memphis, Tenn.	6.04	4.13	5.44	3.36
St. Paul, Minn.	5.13	4.99	4.16	3.10
Detroit, Mich.	3.99	3.17	3.16	2.73
Average for United States	4.84	4.90	4.85	4.79

The U.S. Chamber of Commerce acting through a fire waste council conducts an annual contest among local chambers for superiority in fire prevention activities, awarding prizes therefor. The National Board of Fire Underwriters maintains laboratories for the testing of devices and materials falling within the scope of its services, and makes city surveys covering water supplies, fire department equipment and other similar items.

In most cities desirability of action along the following lines

Canadian Fire Losses

	1922	1923	1924	1925	1926
	\$	\$	\$	\$	\$
Value of property destroyed	54,390,688	48,282,354	45,906,531	40,729,724	38,395,096
Insurance premiums in excess of losses paid	16,529,907	20,472,375	21,590,380	27,246,031	30,884,862
Maintenance cost of municipal fire protection	23,247,950	24,170,420	24,659,204	25,103,246	25,970,803
Installation and maintenance cost of private fire protection	8,431,050	8,873,200	8,994,500	9,374,815	9,846,725
Total	102,599,595	101,798,349	101,150,615	102,453,816	105,097,486

has been indicated: (a) competent inspection by the fire department; (b) a more general use of fire-resisting roof coverings, protected window and door openings and automatic sprinklers; (c) adequate ordinances governing the storage and use of explosives and inflammable substances; (d) adequate means for the conviction of incendiaries; (e) public education in the use of fire-alarms and use of first-aid extinguishing devices. (F. H. WE.)

FIREPROOFING. This term is applied to methods of making normally combustible materials fireproof as far as may be, but in practice the most that can be done with them is to subdue or retard inflammability. The subject is one of great importance, especially in connection with the construction of theatres and other buildings where large numbers of people are collected together and where special illumination is required. The nature of or disposition of materials used in theatres has become the subject of public regulation in many countries and it is usual to provide that no combustible scenery shall be employed unless it has been treated with flame-retarding solutions. The London County Council regulations, for instance, provide that in theatres materials such as wood, canvas, textiles, etc., must be rendered non-inflammable by impregnating them with solutions, and names the following as having been found suitable:—(1) for scenery and coarse fabrics: a solution of 1 lb. of phosphate of ammonia and 2 lb. chloride of ammonia (sal ammoniac) in 1½ gal. water; (2) for delicate fabrics and cotton wool: 10 oz. borax and 8 oz. boracic acid in 1 gal. of water. Stage wood-work must be thoroughly impregnated with phosphate of ammonia. It is, however, quite impossible to make wood-work really fireproof and the council therefore insist, as far as possible, upon the use of incombustible materials such as asbestos.

Such precautions have only been taken in recent times, the London County Council's regulation requiring stage wood-work to be rendered non-inflammable having first come into force in 1901. In 1923 special conditions were laid down with regard to the use of plywood, and at the present time (1928) the construction of theatres is governed by a long series of safety regulations which experience has shown to be necessary. Floors, tiers and roofs, fittings in dressing rooms, all floors and linings to scene stores, workshops, etc., have to be formed of fire-resisting material; soft wood or other inflammable wall linings, decorations, partitions, screens or barriers must not be used, and cavities must not be left behind any linings or decorations. No fire-place may be used and no heating system involving use of a naked flame may be installed in any portion of the auditorium or stage; the stage and cellars below must not be congested with scenery and properties, and the regulations do not stop at fireproofing. There are stringent rules as to hydrants, fire appliances, fire drills, light installations, etc., and it is required that a competent fireman with practical experience in fire prevention and extinction should be on the staff. (A. F. H.)

United States.—The building code recommended by the National Board of Fire Underwriters is commonly used as a basis in the preparation of building ordinances of many cities. A solution which has been widely recognized for the fireproofing of fabrics, is one made of three parts of ammonium phosphate, two parts of ammonium chlorate and one part of ammonium sulphate and about 40 parts of water. Lumber impregnated with fire-retardant chemicals is termed "fireproof wood." The industry had its beginning in the United States in 1895. The principal market for fireproof wood has been in New York city. Its building code prohibits the use of wood for floors and interior trim for buildings in excess of 150 ft. in height unless fireproofed in accordance with rules prescribed by the superintendent. The treatment of the wood is commonly done by impregnating it with fire-retardant chemicals in closed cylinders under artificial pressure. (See TIMBER PRESERVATION.) (C. T. B.)

FIRESHIP, a vessel laden with combustibles, floated down on an enemy's ships to set them on fire. Fireships were used in antiquity and in middle ages. The highly successful employment of one by the defenders of Antwerp when besieged by the prince of Parma in 1585 brought them into prominent notice, and they were used to drive the Armada from its anchorage at Gravelines

in 1588. They continued to be used, sometimes with great effect, as late as the first quarter of the 19th century. Thus in 1809 fireships designed by Lord Cochrane (earl of Dundonald) were employed against the French ships at anchor in the Basque Roads; and in the War of Greek Independence the successes of the Greek fireships against the Ottoman navy, and the consequent demoralization of the ill-disciplined Turkish crews, largely contributed to secure for the insurgents the command of the sea. In

THE CONSTRUCTION OF FIRESHIPS

Fig. 1.—Fireship containing space 1 ft. x 5 ft. filled with gunpowder

Fig. 2.—The same ship equipped with a large sail which, fastened below the middle of the ship, when inflated by the current pulled the craft along

general, however, it was found that fireships hampered the movements of a fleet, were easily sunk by an enemy's fire, or towed aside by his boats, while a premature explosion was frequently fatal to the men who had to place them in position. They were made by building "a fire chamber" between the decks from the forecastle to a bulkhead constructed abaft the mainmast. This space was filled with resin, pitch, tallow and tar, together with gunpowder in iron vessels. The gunpowder and combustibles were connected by trains of powder, and by bundles of brushwood called "bavins." When a fireship was to be used, a body of picked men steered her down on the enemy, and when close enough set her alight, and escaped in a boat which was towed astern. As the service was peculiarly dangerous a reward of £100, or in lieu of it a gold chain with a medal to be worn as a mark of honour, was granted in the British navy to the successful captain of a fireship. A rank of *capitaine de brûlot* existed in the French navy of Louis XIV., and was next to the full captain—or *capitaine de vaisseau*.

FIRE-WALKING, a religious ceremony common to many races, and widespread in all ages. It still survives in Bulgaria, Trinidad, Fiji Islands, Tahiti and India, the Straits Settlements, Mauritius, and Japan. Indian settlers in Natal performed the rite in Pietermaritzburg in the autumn of 1927, in fulfilment of a vow. The details of its ritual and its objects vary in different lands, but the essential feature of the rite, the passing of priests, fakirs, and devotees barefoot over heated stones or smouldering ashes, is always the same. Fire-walking was usually associated with the spring festivals and was believed to ensure a bountiful harvest.

The interesting part of fire-walking is the alleged immunity of the performers from burns. On this point authorities and eye-witnesses differ greatly. In the Natal case no injuries were seen. The bulk of the reports certainly leave an impression that there is something still to be explained in the escape of the performers from shocking injuries. The preparations, perhaps physical in part, produce a feeling of intense nature associated with the phenomenon of possession. In some way anaesthesia is induced.

FIRE-WEED, the name given in the United States to various plants which spring up quickly and profusely in burnt-over areas in forest regions, especially to the great willow-herb (*q.v.*), which almost throughout the continent is exceedingly abundant after forest fires. Its rapid spread is effected by the blowing about of its small downy-tufted seeds by the wind.

FIREWORKS. The history of pyrotechny may be said to have begun when a prehistoric firemaker first mixed saltpetre from his cooking with charcoal from his fire, to use as tinder. In subsequent ages other ingredients were added as pyrotechnic mixtures developed, and eventually, when the principle of the gun was evolved by Berthold Schwartz in the 13th century, the pyrotechnic mixture most suitable for his needs was named gunpowder.

About the date of the introduction of artillery the military fireworker came into existence, whose business was to provide pyrotechnic engines of war, to which duty was subsequently added the provision of spectacular fireworks in celebration of victory or peace. During the 17th and subsequent centuries most occasions

of national rejoicing were celebrated by displays of fireworks; these were generally provided by the military fireworkers.

In earlier displays a limited number of pyrotechnic effects were eked out with others of a scenic or theatrical nature and the use of merely inflammable substances, in the form of torches and flares, which cannot, strictly speaking, be classed as pyrotechnics. It was not until the early part of the 18th century that displays of any considerable pyrotechnic merit were produced.

During the 17th century there were two schools of pyrotechnic thought, that of northern Europe, with Nuremberg as its centre and Clammer as its leader, and the Italian school. The former, although producing probably better results from a purely pyrotechnic point of view, could not vie with the southern school in artistic elaboration and the scenic accessories introduced. In the earlier part of the 18th century the brothers Ruggieri, Bolognese firework artists, attracted no doubt by the lavish expenditure of Louis XV., visited Paris and produced displays at Versailles and elsewhere on a hitherto unprecedented scale. One of the Ruggieris, in conjunction with one Santi, carried out the display in London which celebrated the Peace of Aix-la-Chapelle in 1749, an event which appears to have been celebrated in most of the capitals of western Europe. During the remainder of the century firework displays increased both in number and scale; in addition to official exhibitions celebrating national events, the popular places of resort, the tea gardens and bowling greens began to add fireworks to their list of attractions. Those in the London resorts, Vauxhall, Ranelagh and Marylebone gardens, are still remembered.

As yet no real advance had been made in pyrotechnic mixtures; no colour had been introduced, the art still relied on saltpetre, which had been its foundation. (The importance attached to this salt by early writers, such as Biringoccio, is reflected in the long and elaborate dissertation they give on its preparation and refinement.) Although some pyrotechnists claimed to produce various tints, there is no doubt De Frazier, in his two books published in 1707 and 1747, came nearest to the truth in describing the flame produced by his compositions as "reddish," "greenish," etc.

In the first quarter of the 19th century, however, the era of modern pyrotechny began with the introduction into the art of potassium chlorate, which had been discovered by Berthollet in 1788. Genuine colour effects were now possible and a field of research was opened which, even yet, has not fully been explored. The subsequent introduction of the two metals, magnesium (about 1865) and aluminium (in 1894) also gave a brilliancy never before attained, and added greatly to the variety of effects produced.

The famous displays at the Crystal Palace, near London, instituted in 1865, have been one of the greatest factors in the development of the modern display. Old-fashioned limitations and scenic accessories have been discarded and a scale and method, both in aerial and ground fireworks, have been reached which had never previously been attained, eclipsing any official effort, with the exception of the "National Peace display" in Hyde park in 1919, which was probably the greatest display produced up till that time.

Firework Compositions.—The phenomenon we know as fire is produced by the combination of certain substances, which have a tendency so to do, with oxygen in so rapid a manner as to produce intense heat. When such inflammable substances are set on fire in the ordinary way they obtain the necessary oxygen from the air. The art of the pyrotechnist is in the production of mixtures of ingredients which do not depend on atmospheric oxygen

for their combustion. These mixtures are known as pyrotechnic compositions. Every pyrotechnic composition contains at least one ingredient having a supply of oxygen with which it readily parts and others which receive and combine with that oxygen and in so doing produce the effect for which the particular composition has been designed. The most used oxygen-supplying ingredients are potassium nitrate (saltpetre) and potassium chlorate. Compositions may be divided into two classes, those designed to produce force and sparks and those producing flame, either white or coloured. There are also certain compositions which are designed to produce special effects such as noise, a dense cloud of smoke for military or other purposes, or a whistling sound as that produced by picrate of potash in the familiar whistling rocket.

Force and Spark Compositions.—The basis of these compositions is a mixture of potassium nitrate, sulphur and charcoal, ground to a fairly fine powder. In some cases "mealed," or finely ground gunpowder is added to give extra fierceness when required, as for sky rockets, turning cases (used to turn wheel devices) and similar fireworks. Additional ingredients are included to produce sparks of various forms. The nitrate of lead and barium are also used sometimes in these compositions; also aluminium in an extremely finely divided dust to produce a very brilliant white fire.

Flame Compositions.—In this class are included those compositions which give colour to pyrotechny, the "stars" in rockets, shells and roman candles, the decorations on revolving and stationary devices and set pieces and the outlines in pictorial, or (as they are technically called) lancework pieces. *White Fire*, which varies in its composition according to the purpose for which it is used, generally consists of the ingredients potassium nitrate, salts of antimony, or arsenic and sulphur. With the exception of white fire and a few others of little importance, such as the portfire and blue light used at sea, flame compositions rely for their combustion and their colour on the presence of potassium chlorate, or occasionally perchlorate. *Coloured Fires.* The combustion of potassium chlorate, or perchlorate, in combination with a metal salt has the effect of turning the metal present into a gaseous state and produces a coloured flame. The following are the salts used:—Red, the nitrate, carbonate or sulphate of strontium; green, the nitrate, chlorate or carbonate of barium; yellow, oxalate or carbonate of sodium, and for blue the carbonate, sulphide or arsenite of copper in combination with calomel, mercurous chloride. It is interesting that, although copper burnt in a blowpipe flame produces a green colour, in pyrotechny copper salts are only used to produce blue, as in the presence of chlorine, which must be present with potassium chlorate, the flame is blue; this is deepened by the addition of calomel, which produces still further chlorine.

Magnesium powder is used with colour compositions where extra brilliancy is aimed at. Most colour compositions have, in addition, some burnable substance which serves to increase the mass and effect without detracting from the brightness or colour. The most commonly used are shellac, sterine, sugar of milk, pitch and paraffin. Sometimes the burnable substance serves also as an agglutinant, as shellac and spirit, starch paste, gum water, linseed oil or dextrine.

Firework Cases.—The composition of each firework is enclosed in a "case" formed of paper, pasted and rolled round a cylindrical former; they are either "dry rolled," that is, only the edge of the paper is pasted, or "wet rolled" in which case the paste covers the whole surface of the paper. Generally the case used for force and spark compositions remains intact during the burning of the firework and that enclosing a flame composition is consumed as the firework burns.

Compositions are introduced into the cases in two ways, either by "charging" (when a succession of small quantities of composition are poured in from a scoop of suitable size, each scoopful being consolidated by a number of blows delivered by a mallet on a cylindrical wooden tool exactly fitting the bore of the case, known as a "drift"), or by "filling" with a small copper funnel having a spout of suitable size to fit the case and provided with metal rod of somewhat less diameter than the inside of the spout, having a knob for the hand at the upper end. Composition is placed in the funnel, the spout inserted in the case and a rapid up

CROSS SECTION OF A SKYROCKET
The solid black portion represents the composition, which, when ignited, produces a recoil that starts the rocket on its spectacular upward flight.

MANUFACTURE AND DISPLAY OF FIREWORKS

1. Firework display near the Serpentine in Hyde Park, London
2. A display at the Crystal Palace, London. The displays at the Crystal Palace, which have become world famous, were instituted in 1865. They have been an important factor in the development of modern fireworks
3. View of a modern firework celebration in which rockets, shells and Roman candles are used. The rocket, as shown in this display, is the most elaborately constructed of any firework. It is driven into the air by the recoil produced by a jet of fire thrown out from its burning composition
4. "Fountains of Fire," a Roman candle display at the Crystal Palace
5. A set piece which, when ignited, gives the impression of a racing motor car. These devices consist of frameworks of wood on which are secured firework units connected by a quickmatch
6. Making maroons. The paper or pasteboard shells are first wound with strong twine; they are then filled with the explosive and the fuse is attached. In this work manual methods have never been satisfactorily replaced by mechanical means

and down movement of the rod alternately releases a small quantity of composition and consolidates it in the case. This method is only used with cases of small diameter.

It may be as well to mention here that these manual methods have never been superseded satisfactorily by mechanical means, although many experiments have been made. In pyrotechny, as in some other crafts, hand work maintains its superiority.

Rockets.—The rocket, which is the most elaborate in construction of any single firework, also requires the highest degree of technical skill in manufacture. The sky-rocket (its most familiar form) is driven into the air by the recoil produced from a jet of fire thrown out by its burning composition. In order to make this jet as strong as possible the case, which is wet rolled, is choked, or constricted, by pulling in with a cord near one end before drying. In addition, the composition is so charged into the case that a conical cavity is left from the choke or vent, nearly to the top of the case; by so doing, when the rocket is ignited, as large an area as possible of composition is burning at the moment when it is required to give the rocket its initial impetus. This cavity is produced by charging the rocket on a tapering spindle and using drifts of varying lengths, pierced with a hole of suitable size. Above the composition in the body of the rocket is a diaphragm of compressed clay, bored with a central hole through which the fire from the top, or "heading," of the composition is communicated to the "garniture" contained in a case, usually in the form of a truncated cone, which forms an extension of the body of the rocket and is known as the "cap." The garniture consists of "stars" of colour, or other suitable composition, either contained in short cylindrical cases, when they are known as "pinched stars" from their method of manufacture, or compressed into cylindrical form without a case, when they are known as "pumped stars." *Gerbs and Fountains* are charged without a central cavity, the choke generally being formed by a clay diaphragm. The compositions are similar to those of the rocket, with the addition of spark-producing ingredients. The composition for gerbs (formerly known as Chinese fire) contains iron filings; for fountains (formerly known as brilliant fire) steel filings; and for flower pots, lampblack, producing remarkable sparks, which, from their form, gave to this composition the name of spur fire. *Devices and Set Pieces* consist of frameworks of wood on which are secured firework units which are connected together by quickmatch and take the form of wheels moving in the vertical or horizontal plane; stationary, or, as they are called, fixed devices, of various geometrical forms; waterfalls; tree pieces and "lancework" pieces. The outline of a lancework piece is constructed in cane on a wood lattice framework and the design picked out in appropriate colouring with lances (small cases of colour, or "bright" composition, about the size of a cigarette); by this means almost any pictorial design can be carried out. At the Crystal Palace, London, where this type of set piece has been most highly developed, pictures have been produced over 600ft. long and 50ft. high, carried out entirely in lines of fire.

St. H. Brock, *Pyrotechnics, The History and Art of Pyrotechny* (containing a complete bibliography) (1922). (A. St. H. B.)

FIRM, originally dense or close; hence steady, unchanging or fixed. From a late Latin use of *firmare*, to confirm by signature, *firma* occurs in many Romanic languages for a signature, and the English "firm" was thus used till the 18th century. From a transferred use came the meaning of a business house. In the Partnership Act, 1890, persons who have entered into partnership with one another are called collectively a firm, and the name under which their business is carried on is called the firm name.

FIRMAMENT, the sky, the heavens. In the Vulgate the word *firmamentum*, which means in classical Latin a strengthening or support (*firmare*, to make firm or strong) was used as the equivalent of *στερέωμα* (*στερέειν*, to make firm or solid) in the Septuagint, which translates the Heb. *rāqīya'*. The Hebrew

probably signifies literally "expanse," and is thus used of the expanse or vault of the sky, the verb from which it is derived meaning "to beat out." In Syriac the verb means "to make firm," and is the direct source of the Gr. *στερέωμα* and the Lat. *firmamentum*. In ancient astronomy the firmament was the eighth sphere containing the fixed stars surrounding the seven spheres of the planets.

FIRMAN, an edict of an oriental sovereign, used specially to designate decrees, grants, passports, etc., issued by the sultan of Turkey and signed by one of his ministers. (The word is an adaptation of the Per. *fermān*, a mandate or patent.) A decree bearing the sultan's sign-manual and drawn up with special formalities was termed a *hatti-sherif*, Arabic words meaning a "line, writing or command," and "lofty, noble." A written decree of an Ottoman sultan was termed an *irade*, the word being taken from the Arab. *irādā*, will, volition, order.

FIRMICUS, MATERNUS JULIUS, a Latin writer, who lived in the reign of Constantine. His *De erroribus profanarum religionum*, written c. 346 and still extant, attacks the false objects of worship among the Oriental cults and discusses a number of formulae and rites connected with the mysteries. Its declamatory tone contrasts with his eight books on astronomy (*Libri VIII. Matheseos*) written c. 336.

The best editions of the *De Erroribus* are those by C. Bursian (Leipzig, 1856); by C. Halm, in his *Minucius Felix* (*Corp. Scr. Eccl. Lat. ii.*) (Vienna, 1867); and by K. Zeigler (1907). The astronomical work was first printed at Venice in 1499, the last edition being by W. Kroll and F. Skutsch (Leipzig, 1897-1913). See G. Ebert, *Gesch. der chr. lat. Litt.* (ed. 1889); O. Bardenhewer, *Patrologie* (ed. 1901).

FIRMINY, a town of central France in the department of Loire, 8 m. S.W. of St. Etienne by rail. Pop. (1926) 18,192. It has important coal mines known since the 14th century and extensive manufactures of iron and steel goods.

FIRST AID TO THE INJURED. First aid refers to measures to be taken immediately after an accident not with any idea of cure but in order to prevent death by prompt action, or in less dangerous cases to prevent further harm being done, and put the victim in the best possible condition for later and more extensive treatment.

General Directions for Giving First Aid.—The American Red Cross gives the following brief summary of first aid instruction for cases of emergency: (1) one who understands first aid, or the person in authority, should take charge; (2) keep cool; (3) keep the crowd away; (4) send for a doctor or ambulance; (5) meantime do what you can to help the victim. Unless special attention is needed, proceed to put the patient in a safe and comfortable position, which usually is lying down with head low, although, if the face is flushed, the head should be raised on a pillow. To avoid the possibility of choking never attempt to give water or stimulants to an unconscious person. In all serious cases, be sure to keep the patient lying down. Other important points to remember are: loosen tight clothing; avoid giving whiskey or brandy; but cold water may be given slowly if the patient can swallow; rip or cut clothing away to examine injury. Avoid disturbing the patient, especially in the case of fracture, when the patient should not be moved before the bone is set, unless absolutely necessary; keep the patient warm, especially in case of severe shock.

Treatment for Shock.—Shock is present to some degree in all serious injuries, being greatly increased by severe bleeding and pain. Shock may be recognized by pallor of the face, clammy skin, rapid weak pulse and shallow breathing of the patient. After calling a doctor the first essential of treatment is to keep the patient warm with blankets, hot water bottles, hot drinks, etc. (being careful to avoid scalds and burns). If the patient is conscious, about a cupful of hot strong coffee, hot milk, or hot water, containing a half teaspoonful of aromatic spirits of ammonia, may be used as a stimulant, and repeated in a half hour if necessary, remembering always never to pour liquid down the throat of an unconscious person. Place the patient on the back with the head low and the clothing loosened around the neck, chest and abdomen. In case of the presence of some more severe symptom than shock, such as dangerous bleeding, that should of course receive

first attention.

Fractures.—Among the most common severe injuries are fractures; *i.e.*, broken bones. While a fracture is not always easily recognizable, symptoms are a localized pain, tenderness, limitation of motion or deformity of a part, a grating sound from the broken ends, or an inequality of the bone which sometimes may be felt through the skin. A fracture must be set as soon as possible, of course, but because of the danger of further injury to tissues from the sharp edges of the broken bones, treatment before the doctor's arrival best consists chiefly in very careful handling of the injured part, and the application of a simple splint to hold the part in position. Splints may be improvised from narrow boards, heavy pasteboard, umbrellas, canes, and the like, but must be padded when applied next to the skin, must not be bound so tightly as to restrict circulation and should be long enough to prevent movement at the nearest joints. In any case of fracture, the patient should not be moved before the broken bone is firmly held in a splint. Although it may be possible and even necessary, if a physician cannot be reached, for the first aider to set the bones, the danger of cutting tissues in exerting sufficient force to bring the ends together is so great that whenever possible it is much better to await a physician's treatment. If in addition to the break there is a wound leading down to the broken bone, or a broken end of bone protruding through the skin, a compound fracture has occurred, and must first be treated as a wound (*see* "Wounds"). In such cases always treat the patient for shock, and be sure to let nothing touch the abrasion but a surgically clean dressing. In fractures of collar bone, ribs, jaw, nose, etc., bandaging obviously must be substituted for splints. If fracture of the skull is possible, the patient should be placed lying down with head slightly raised, and treated for shock until the doctor's arrival. No stimulant should be given unless the patient is very weak, in which case spirits of ammonia may be used.

Dislocations.—Dislocations of jaw and of the fingers, except that of the second joint of the thumb, which must be treated by a doctor, may be successfully reduced by the first aider, if care is exercised. In case a finger is dislocated, simply grasp firmly on the hand side, and pull the end straight out away from the hand. The bone will usually slip easily into place. In case of a dislocation of the jaw, the thumbs of the person giving first aid should be well wrapped, placed on the back teeth with fingers grasping the outside of the lower jaw. Pressure exerted first down and then backward will usually cause the jaw to snap into place, so that the one giving the treatment should be careful to avoid having his thumbs caught by the snap. A dislocated shoulder should always have a physician's attention within four hours.

Sprains.—Sprains, which are injuries of the joints, causing severe pain and swelling, should be treated immediately and a doctor called. Absolute rest is necessary. The joint should be elevated and when possible heat or cold applied, heat being preferred in case of severe shock or if the patient is a child or an older person. This treatment should continue for from 24 to 28 hours.

Wounds.—Wounds, including all injuries in which the skin is pierced or broken, always involve the danger of pus germs entering from outside the body. As there is no danger from pus germs in the air or within the body, they must come from the surface of the body or from foreign objects. For this reason a wound which bleeds freely lessens danger by carrying out foreign germs in the wound. The vast majority of wounds wherein bleeding is comparatively slight chiefly require that the surrounding clothing be removed and that nothing be allowed to touch the wound. If a physician is called, a course which should be adopted in the case of every deep wound, nothing further should be done. Exposure to air is much safer than application of anything not surgically clean. It is desirable to make an ordinary wound bleed sufficiently to cleanse itself. Adhesive plaster should never be used to cover directly anything more than a trivial scrape. Nearly all wounds require a dressing, which must be surgically clean and should cover the wound thoroughly. If foreign bodies, such as splinters, remain in the wound, they should be gently pulled out. In removing a splinter from under a nail, put a knife blade against the splinter, holding it on the blade with the thumb nail after scraping the

injured nail thin and cutting out a small V-shaped piece in order to reach the splinter. Small splinters may be removed with a needle. All care should be taken to avoid infection, using preferably iodine to sterilize. (*See* "How and When to Use Iodine.") Also it should be remembered that the majority of serious cases of blood poisoning result from quite small cuts or scratches.

Haemorrhages or Severe Bleeding.—In the event of severe bleeding (haemorrhage) the patient should be kept lying down with head low, be kept warm, have plenty of good air to breathe and be supplied with stimulant only if absolutely necessary. The bleeding can usually be stopped by the application of a small pad of gauze and a tight bandage over the wound or by pressure with the thumbs on the main blood vessel between the wound and the heart, the limb being at the same time elevated—if it be a limb which is involved. The points for pressure are just in front of the ear (for bleeding from the temples); the inner side of the arm below the arm pit, about where the inner seam of a shirt comes; the inner side of the thigh near the groin; and in the hollow back of the knee. In arterial bleeding a tourniquet should be used. This may be improvised from a handkerchief in which a small stone or other hard object has been wrapped. The tourniquet should at all times be applied between the wound and the heart, with the hard object above the wound, and twisted with a stick until the constriction shuts off the bleeding. Care should be taken always to loosen the tourniquet every 15 minutes in order to avoid death of the part resulting from complete loss of circulation. When the tourniquet is loosened watch closely to see if bleeding has stopped. If so it may remain loosened. Bleeding from veins can usually be checked by applying a compress tightly to the wound, but lacking a surgically clean compress and if severe bleeding is present, pressure must be made with the fingers, at the risk of infecting the wound. Any tight bands preventing the return flow of blood to the heart should be loosened immediately, and if the injury is in a limb it should be elevated. A doctor should always be called. If there is internal haemorrhage the patient should lie down, with his head lower than his body, a doctor should be sent for, and in the meantime ice or a cloth wrung out in very cold water should be applied to the point from which the haemorrhage seems to come. The proper application of bandages requires special study (*see* BANDAGE).

Nose Bleeding.—In severe nose bleeding, the patient should be placed in a chair, with his head hanging backward and any tight clothing round his neck loosened, and cold applied to the back of his neck by means of a key, or cloth wrung out in cold water. A roll of paper placed under the upper lip, between it and the gums may help. If bleeding continues, salt and water, one teaspoonful to a cup of water, should be snuffed up the nose. If bleeding still continues call a doctor, plug the nostril with a small piece of cotton or gauze, and pinch the soft part of the nose below the bone. Do not give stimulants.

Burns.—For slight burns, common baking soda, dry or dissolved as a paste, may be applied, or picric acid gauze, wet with water or 2% solution of picric acid, or plain gauze may be used. Extensive burns on which blisters have formed should be covered, preferably with gauze or a clean soft cloth saturated with baking soda solution, carbolized vaseline, unguentine or, in an emergency, any clean pure oil. Deep burns require prompt attention from a physician. A solution of Epsom salts makes a soothing dressing. If burns come from acids they should be washed off under a water tap as quickly as possible and then washed with lime-water, or baking soda and water or even soap-suds may be employed. For burns from carbolic acid, alcohol should be applied freely. Burns from alkalis should be washed, in the same way as acid burns, and neutralized by vinegar, lemon juice or hard cider. In all burns use care in removing clothing, cutting away around the burn, but never pulling. Clothing that sticks should be soaked off later with oil. Never place cotton over a burn.

Sunstroke.—If sunstroke has occurred, the face will be hot, flushed and dry. The patient should be cooled as quickly as possible. Cracked ice or cloths wrung out in cold water should be applied, especially to the head, which should be slightly raised—the patient, of course, lying down. When conscious, he may drink

cold water freely. If he is rubbed constantly to bring blood to the surface and to avoid shock, he may be wrapped in sheets wrung out in cold water or put in a very cold bath. No stimulants should be used.

Heat Exhaustion.—Heat exhaustion, which must be distinguished from sunstroke, causes the skin to be pale, cold and moist, and should be treated in the same manner as shock (*see* "Treatment for Shock").

Frost-bite or Freezing.—The experience of arctic explorers has demonstrated that rubbing after freezing has taken place is not the treatment. Rubbing with snow is especially bad. Gently cover the frozen part with the hand or other body surface until it is thawed, or the frozen part may be thawed very gradually in cool air or cold water. If this cannot be done cover with extra clothing until thawed.

Artificial Respiration.—The essential treatment in all forms of suffocation, whether from water, gas, smoke or shock from electrical contact, is artificial respiration. (For explanation and description of this process *see* ARTIFICIAL RESPIRATION.)

Gas Poisoning.—Gas poisoning, commonly resulting from leaking fixtures, or from the fumes of an automobile exhaust (the deadly carbon monoxide gas) causes suffocation, headache, dizziness, nausea, vomiting and extreme sleepiness. The pulse is fast and breathing weak and rapid. This poisoning is rapidly fatal. The victim should be quickly carried to fresh but not cold air, as cold will kill a gassed person from shock. If needed, artificial respiration should be given at once. If the patient is conscious, strong coffee should be given liberally, or some other stimulant may be substituted. The patient should be kept warm and not allowed to exercise. A doctor's services must be procured to avoid the danger of pneumonia.

Electric Shock.—In cases of electric shock, the victim must be quickly released from the current by using a dry non-conductor (rubber gloves, several thicknesses of newspaper, dry clothing, a wool cap or felt hat wrapped around the hand, a rope or a dry board may be used). Thus the wire, if on top of the victim, can be quickly flipped off with any board or stick, or an instrument with a wooden handle may be used to cut it. Alternatively, it may be short circuited by dropping a metal bar on it between the victim and source of the current; or the former may be removed by lifting, care being taken that the rescuer stands on a dry non-conducting surface and uses no metal or anything damp or moist in doing so. After the victim is released, artificial respiration and treatment for shock should follow.

Drowning.—To administer efficient first aid in drowning requires special knowledge and skill. (For discussion of methods of actual rescuing from the water *see* LIFE SAVING SERVICE; DROWNING AND LIFE SAVING.) It may suffice to say here that after the body has been secured, artificial respiration, in charge of someone who understands it, should be immediately tried, any water or mud having first been removed from the mouth and a doctor, of course, being sent for. (*See* ARTIFICIAL RESPIRATION AND DROWNING AND LIFE SAVING.)

Unconsciousness.—Unconsciousness may be the result of a large number of causes. Unless special treatment be required for poison, bleeding, sunstroke or suffocation, the procedure is to place the patient prone with head low, and, if the face be pale and the pulse weak, to warm and stimulate him in every way possible. If, however, as sometimes happens, he is red-faced, with a strong pulse, he should be placed prone, head raised, cold water should be sprinkled on the face and chest and no stimulants applied. In any case of fainting, windows should be opened, clothing loosened and smelling salts or ammonia used. Taking the person who feels faint into cold fresh air, or making him double over with his head between his knees for a moment, sometimes will avert a faint.

Convulsions.—If a person is seized with convulsions, do not attempt to hold him, but put him on the ground or floor where he cannot injure himself by thrashing about and place a piece of wood covered with a handkerchief in the mouth to prevent him from biting his tongue.

Apoplexy and Brain Injuries.—In the case of apoplexy and brain injuries send for the doctor at once, giving the patient in

the meantime complete rest and quiet, if possible in a darkened room, with the head and shoulders raised on a pillow. Cold cloths may be applied at the same time to the head and hot water bottles to the limbs but no stimulants should be given.

Alcoholic Poisoning or Drunkenness.—Alcoholic poisoning or drunkenness must never be confused with apoplexy. If in doubt as to which condition is present treat for apoplexy and be careful not to cause vomiting. For drunkenness give an emetic, such as mustard and water or quantities of lukewarm water, followed by strong coffee or aromatic spirits of ammonia. Apply hot water bottles and rub the limbs towards the body to increase circulation.

Opium Poisoning.—Poisoning from preparations of opium, of which laudanum and morphine are the most common, should be treated, while awaiting a physician, with an emetic (mustard and water or quantities of lukewarm water) to provoke profuse vomiting. Plenty of strong coffee should be given, and an adult may be slapped with a wet towel, or threatened, to rouse him. Unless weak, he may be walked up and down, but at any signs of weakness he should be made to lie down.

Carbolic Acid Poisoning.—In carbolic acid poisoning, Glauber's or Epsom salts are fair antidotes, or lime water, though less efficient, may be used as a mouth wash and swallowed. Raw eggs, castor oil or sweet oil may be given, and stimulants and warmth should always be included in the treatment. In general, in cases of poisoning, the first step is to send for the doctor, telling him if possible what poison has been taken. Then give an emetic, and antidote, with the doctor's advice. (*See* table of antidotes, etc., under ANTIDOTES.)

Home and Camp Emergencies.—For the numberless small emergencies of home, camp and sports which arise, a few simple bits of first aid knowledge often save discomfort and sometimes avert serious consequences.

Common Cramps. Common cramps of the abdomen, usually due to indigestion or chill, should be treated by gentle rubbing and application of the hot water bottle. For internal relief a soda mint tablet may be given. Cathartics immediately or forced vomiting are not recommended because of the possibility of appendicitis. For nausea and vomiting, drinking lukewarm water freely causes vomiting and washes out the stomach. Following this the patient should lie down in a cool place, hot fomentations should be applied to the abdomen, and a little soda mint may be taken. Cramps in the legs should be treated by rubbing and kneading.

Hiccupping. Hiccups can usually be stopped by holding the breath long enough so that the air in the chest forces the diaphragm down and prevents it from contracting. This may be done by drinking a large glass of water in small sips, without taking a breath. If necessary, vomiting will always cure hiccup by removing the cause of irritation from the stomach.

Convulsions in Children. Convulsions in children always require treatment by a doctor. Until his arrival absolute quiet for the patient is necessary, and cold cloths or an ice cap should be applied to the head, with a mustard pack surrounding the body to bring the blood to the skin. Disturb the child as little as possible.

Toothache. If toothache begins at a time when it is impossible to reach a dentist immediately, clean out the cavity if accessible and place a small piece of cotton, dipped in oil of cloves, in the cavity, with a toothpick or needle. If treatment must be through the gum, use absorbent cotton soaked in spirits of camphor as an emergency measure.

Earache. For emergency and temporary treatment of earache, hot cloths or hot water bottles, or fumes from hot alcohol poured on a cloth and held outside the ear may be of help. A few drops of hot sweet oil not hot enough to burn, dropped in the ear, the ear then being plugged with cotton, may give temporary relief but the earache should be treated as soon as possible by a physician.

Sties. Pain from a sty may be diminished by holding to the eye a cloth wet with water as hot as can be borne.

Prickly Heat. Prickly heat is often relieved by a good talcum powder, but if severe it should be bathed with a mixture of one part alcohol to three of water, and afterwards dusted with talcum.

Lime-water with two drops of carbolic acid to the ounce is an excellent application for prickly heat. These applications should always be used after bathing.

Hives (*Urticaria* or *Nettle-rash*). In severe cases of hives a doctor should be called. Ordinarily an emetic should be taken followed by a purgative such as Rochelle or Epsom salts. To relieve itching, a warm bath containing a handful of washing soda may be given, or bathing the parts with a strong solution of bicarbonate of soda and water, or rubbing with spirits of camphor, may give relief.

Mosquito Bites. Mosquito bites are best treated with ammonia, or lime-water containing two drops of carbolic acid. The application of cool, wet dressings may help.

Ivy or Oak Poisoning. Severe ivy or oak poisoning should be treated by a doctor, but the application of a simple wash of 3% boracic acid solution, with carbolized vaseline as an ointment affords relief, the treatment being repeated daily. Epsom salts solution is also recommended.

Blisters. Blisters on the hands or feet are best treated by washing the part thoroughly in hot water, pricking the blister through the skin at the side with a clean needle and gently pressing out the fluid.

Snake Bites. Snake bites are comparatively rare injuries but may be rapidly fatal. In the United States, the rattlesnake and moccasin are most to be feared. The treatment consists in immediately circling the wounded part with a tightly tied string, handkerchief, or bandage, between the bite and the body, if the bite is on a limb, thus preventing absorption of the poison by cutting off the return of blood to the body. Soak the wound in hot water and squeeze or suck it as it is absolutely essential to extract as much of the poison as possible. There is little danger in sucking wounds made by the poisonous snakes in the United States, unless there is a cut or infection in the mouth. Then cauterize or burn the wound, using ammonia or permanganate of potassium freely, in strong solution. Dose freely with strong stimulants such as aromatic spirits of ammonia. Do not fail to loosen the tight bandage after one hour, loosening it a little at a time, and observing the effect of the poison thus let into the blood-stream on the patient. Tighten again and repeat the loosening process. If the poison should cause severe depression, care should be taken to keep the wound tightly tied up regardless of the danger of the part dying from lack of circulation.

Dog and Cat Bites. Treatment for dog and cat bites is the same as for snake bite, except that the bandage may be removed as soon as the wound is cauterized. A doctor should be consulted and every effort made to discover whether or not the animal was rabid; if so every measure for the prevention of hydrophobia must of course be taken.

Insect Bites. In general, for the bites of insects and spiders, ammonia should be applied and care taken to ensure that the sting does not remain in the wound.

Eye Injuries. In any injury of the eyeball, cover both eyes with absorbent cotton or soft cloths, soaked in cool water, so as to keep the eyelids still, and bandage them into place with head bandages, being careful not to bind tightly enough to cause pressure on the eyeballs. They should then be kept constantly cooled with water till a doctor can be procured. Splinters in the eye should be pulled out if possible. A little olive- or castor-oil in the eye may help. If foreign bodies, such as cinders, sand or dust get in, never rub the eye, but first close it to allow tears to accumulate which may wash the object into view so that it may be removed with a bit of clean cloth or cotton. Failing in this, pull the upper lid over the lower two or three times, close the nostril on the opposite side with the finger and blow the nose hard. If the offending object is still in the eye, examine first the lower lid by pressing down and then the upper lid. To do this last, seat the patient in a chair, head bent backward, and standing behind him place the finger or a match on the upper lid, $\frac{1}{2}$ in. from its edge. Turn the upper lid back and if the foreign body can be seen brush it off with a bit of clean cotton. Particular care must be taken to avoid any rough treatment and in case of any difficulty the eye should be bandaged as above instructed, and a doctor called.

How and When to Use Iodine.—Iodine is the only disinfectant suitable for general use which is of sufficient strength to be efficacious. Painting iodine on wounds is unquestionably of value in preventing infection, but only if applied within two hours after the accident. It will probably not reach the tissues in a very deep wound, however, and will not prevent pus infection if the tissues are extensively crushed. The best iodine solution is Lugol's, a weak solution of iodine crystals with iodide of potassium in water. Tincture of iodine (a 7% solution) is, itself, too strong and must be diluted with one part alcohol to one of tincture. It should never be used in a stronger solution than this. The method of applying is to paint it on freely with a camel's hair brush or cotton wool on a stick. Do not pour iodine into a wound or cut, and never use it on or near the eyes. Use a rubber plug in the bottle.

Carrying Sick or Injured Persons.—Before attempting to carry a sick or injured person, loosen any tight clothing and see that the patient is warm. In case a stretcher is needed it may be improvised by the use of a pair of poles and two suit coats. The sleeves are first turned inside out and the coats placed on the ground, with the lower edges touching each other, the poles are then passed through the sleeves on each side, the coats buttoned and the buttoned side turned down. A stretcher may also be improvised from a large blanket or rug, in which the poles have been rolled from the outer edge inwards until firmly held, leaving about 20 in. between the two poles, the whole being then turned over. In case narrow blankets are used the edges should be bound to the poles with twine.

Household Medicine Cabinet.—For the household medicine cabinet, the Red Cross recommends the following standard supplies, which are best kept in a white enamelled box, provided with lock and key:—

Aromatic spirits of ammonia, 2oz.	Antiseptic gauze, 1 small package.
(rubber stopper).	Absorbent cotton, $\frac{1}{2}$ lb.
Olive oil, 2 drams.	Roller bandages, gauze, 6—3 large
Epsom salts, 4oz. (or 6 Seidlitz	and 3 small.
powders).	Collodion, 1 small bottle with
Lime-water, 2oz.	brush.
Mustard, powdered, 2oz.	First aid outfits, Red Cross, 2.
Syrup of ginger, 2oz.	Tooth plasters, 1 box.
Syrup of ipecac, 2oz.	Corn plasters, 1 box.
Witch hazel, 4oz.	Glass and spoon, 1 each or medicine
Bismuth subnitrate tablets, 5 grain	glass.
(100 tablets in bottle).	Scissors, 1 pair.
Carbolized vaseline or petrolatum,	Pins, ordinary and safety.
1 tube.	Iodine, one-half tincture with
Oil of cloves, 1 dram bottle	one-half alcohol, 2oz. in bottle,
(labelled "poison").	rubber stopper.
Soda mint tablets, 100 tablets in	Iodine swabs, 6.
bottle.	Bottle, 2oz., 1.
Talcum powder, 1 tin.	Camel's hair brush, 1.

. A convenient first aid kit obtained from the Red Cross or easily made at home consists of a white enamelled tin box with a tight fitting cover, containing:

2 triangular bandages.	1oz. aromatic spirits of ammonia
2 roller bandages.	(rubber stopper).
2 packages of dressing.	2 or 3 safety pins.
1 small roll of absorbent cotton.	Small scissors.
$\frac{1}{2}$ oz. of iodine (rubber stopper in	First aid text-book, with list of
bottle).	contents pasted on inside cover
	of box.

See *American Red Cross Abridged Text-book on First Aid* (3rd general edition). See also RED CROSS. (M. J. S.)

FIRST BANK OF JAPAN. The Japanese name of which this is the convenient English equivalent is *Dai Ichi Ginko Kabushiki Kaisha* (the Number 1 Bank Joint Stock company). It was founded in July 1873, and was the first private bank in Japan.

In 1872 the Japanese Government had promulgated the National Banks Regulations, which were modelled on the National Bank Act of the United States. But these regulations applied only to the national banks; meanwhile, private banks and banking companies began with the founding of the Dai Ichi Ginko, and, 11 years after this inauguration of private banking enterprise, private banks numbered 954. For some time there were

no general provisions to control such banks and companies, beyond their subjection to the control of the local authorities. To bring them under more efficient control, the Ordinary Banks Regulations and the Savings Banks Regulations were promulgated in 1890 and put into force three years later.

The First Bank of Japan, therefore, led the way as a financial organ of general trade. It introduced several innovations and differences from the procedure followed by the national banks. The year 1899 saw the conversion of all the existing national banks into private banking organizations, a process which had been steadily proceeding as the charters granted to the former fulfilled their periods. At this time all banks became subject to the general banking laws, and ordinary banks are now under the control of the minister of finance. In March 1927 a new act was promulgated and it came into force on Jan. 1, 1928; by this act all banking organizations were brought into closer and more uniform relations.

The capital of the First Bank (paid up) was, in Dec. 1928, 57,500,000 yen. The reserves of the bank at the same date totalled 61,550,000 yen. (S. YA.)

FIRST-FOOT, in British folk-lore, especially that of the north and Scotland, the first person who crosses the threshold after midnight on Christmas or New Year's Eve. Good or ill luck is believed to be brought the house by First-Foot, and a female First-Foot is regarded with dread. In Lancashire a light-haired man is as unlucky as a woman. In Worcestershire luck is ensured by stopping the first carol-singer who appears and leading him through the house. In Yorkshire it must always be a male who enters the house first, but his fairness is not considered an objection. In Scotland the custom of first-footing was always more elaborate than in England, involving a subsequent entertainment.

FIRST INTERNATIONAL: see INTERNATIONAL, THE.

FIRST OFFENDER'S ACT: see CHILDREN'S COURTS.

FIRST OF JUNE. The battle of the Glorious First of June was so named because it was fought at a point over 400m. from the mainland and reached a decision on June 1, 1794. It arose out of an attempt by the British to intercept, and by the French to protect, a large consignment of corn which the latter, faced by famine as a result of the bad harvest of 1793, had purchased in America. This convoy, consisting of over 100 vessels, sailed from the Chesapeake at the beginning of April 1794, protected by Admiral Vanstabel with four battleships. Villaret-Joyeuse, the French commander-in-chief at Brest, intended to meet him with his main fleet in the latitude of Brest, some 400m. from the coast. He sent out five ships as forerunners on April 10, and himself prepared to follow as soon as possible. Lord Howe, commanding the British Channel fleet, sailed from Spithead on May 2, with 34 sail of the line; unfortunately he was hampered with a convoy, and was forced to detach eight ships for its protection; but six of them were to rejoin him with all speed after reaching the latitude of Cape Finisterre.

Howe, with the remainder of the fleet, was off Ushant on May 5, and there ascertained that Villaret had not sailed. Not wishing, however, to prevent him from doing so—for he was as willing to fight Villaret as to capture the convoy—he made no attempt to watch Brest, but advanced in a westerly direction along the 47th parallel, thus putting himself between the convoy and the main French fleet. Meeting with no one, he eventually returned to Ushant, arriving there on the 19th, and finding Brest empty. Villaret had sailed on the 16th with 25 ships—he was shortly joined by one of his advance guards—and had passed close by the British fleet in foggy weather. Howe, without even waiting for the six ships which were to have rejoined him next day, immediately turned in pursuit.

Early on May 28, the French were sighted some ten miles to windward. The British were further from Brest than they, which seems to have puzzled Villaret, who, as soon as he had definitely ascertained the position, began to retreat. But Howe, who had collected his fastest vessels into a flying squadron, signalled a general chase, and several English ships got into action with the rear French ship, the enormous "Révolutionnaire," which was made

unfit for action at the expense of a smaller English vessel. On the 29th, Howe, who naturally desired the windward position—especially in view of the particular plan which he wished to put into execution—determined to break the French line from to-leeward. His van ships failed to pierce the enemy, but Howe himself in the "Charlotte," stationed in the centre, broke through the French line towards the rear, and was followed by several of his ships. In the process they surrounded the three rearmost of the French, and Villaret, in order to save them, was compelled to run to leeward. He was too late to prevent them from being rendered unfit for further immediate fighting. The British thus gained the weather-gauge and had, in two days, reduced Villaret's strength to 22, while they themselves still had 25 fit for action. The 30th was foggy, and Howe was content to keep contact with Villaret, who edged to leeward, hoping to meet the remaining four ships of his advance squadron. This he was fortunate enough to do. On the 31st the fog cleared at mid-day, but Howe preferred to postpone his final attack until June 1.

Lord Howe's plan, which he executed on the final day of the battle, was designed to overcome the French withdrawing tactics so often employed by them. Operating from the leeward position, the French would fire at the masts and sails of the British as they advanced, retreating as soon as the latter approached close range, and repeating this manoeuvre till the British were rendered immobile. Howe, instead of engaging the French on the same tack while still to windward, proposed to break through their line at all points, and engage from to-leeward, thus preventing their retreat. This was a counsel of perfection, for not every ship could be expected to break through, but each one that did would prevent the withdrawal of the corresponding Frenchman. The attack produced a mêlée during which seven or eight British ships broke through, and the result was the capture of six French ships and the sinking of another. Villaret succeeded in drawing off the remainder, and the British pursuit lacked direction, Howe, who was nearly 70, being exhausted after five days and nights with no rest. The convoy escaped capture; but the British, who were depressed with the lack of success attending the war on land, were disposed to forgive this oversight in their jubilation at obtaining a first-class victory at sea.

FIRTH, SIR CHARLES HARDING (1857–), British historian, was born at Sheffield on March 16, 1857, and was educated at Clifton and Balliol college, Oxford. He became a fellow of All Souls, Oxford, in 1901, and regius professor of modern history at Oxford in 1904. On his retirement in 1925 he became professor emeritus. Firth's historical work was almost entirely confined to English history during the time of the Great Civil War and the Commonwealth; and his books are of great value to students of this period. The chief of them are: *Life of the Duke of Newcastle* (1886); *Scotland and the Commonwealth* (1895); *Scotland and the Protectorate* (1899); *Narrative of General Venables* (1900); *Oliver Cromwell* (1900); *Cromwell's Army* (1902); *The Last Years of the Protectorate* (1909); *English History in English Poetry* (1911); *Modern History in Oxford, 1841–1918* (1920); and the standard edition of *Ludlow's Memoirs* (1894). He also edited the *Clarke Papers* (1891–1901), and Mrs. Hutchinson's *Memoirs of Colonel Hutchinson* (1885) and wrote an introduction to the *Stuart Tracts* (1903), and contributed to the *Dictionary of National Biography* and the *Cambridge Modern History*.

FIRTH, MARK (1819–1880), English steel manufacturer and philanthropist, was born at Sheffield on April 25, 1819, the son of a steel smelter. At the age of 14 Mark, with his brother, left school to join their father in the foundry where he was employed, and ten years later the three together started a six-hole furnace of their own. Their huge Norfolk works were erected at Sheffield in 1849, and still greater ones were afterwards acquired at Whittington in Derbyshire, and others at Clay Wheels near Wadsley. Mark Firth made many benefactions to the town of

Sheffield, and on his death on Nov. 28, 1880, was accorded a public funeral.

FIRUZABAD, a town of Persia, in the province of Fars, 72 m. S. of Shiraz, in $28^{\circ} 51'$, at an altitude of 4,180 ft., in a fertile plain, 15 m. long by seven, well watered by a river which flows through it from north to south. Pop. about 4,000, according to Lorini (1900). The town is surrounded by a mud wall and ditch. The district has 20 villages and produces much wheat, and the rice of Firuzabad is famous. Three or four miles north-west of the town are the ruins of the ancient city and of a large building popularly known as the fire-temple of Ardashir; beyond them on the face of the rock in the gorge through which the stream enters the plain are two Sassanian bas-reliefs. The river leaves the plain at its southern end, and according to Persian history it was there that Alexander the Great, when unable to capture the ancient city, built a dyke across the gorge, thus damming up the water of the river, turning the plain into a lake, and submerging the city and villages. The lake remained until the beginning of the third century, when Ardashir, the first Sassanian monarch, drained it by destroying the dyke. He built a new city, calling it Jur or Gur, and made it the capital of one of the five great divisions of Fars. Firuz (or Piruz), one of Ardashir's successors, called the district after himself—Firuzabad—("the abode of Firuz"), but the name of the city remained Gur until Azud-ud-Dowleh (949-982) changed it to its present name. (P. Z. C.)

FIRŪZKŪH, a small province of Persia, with a population of about 5,000. Its chief place is a village of the same name situated in a valley of the Elburz, about 90 m. E. of Teheran, at an elevation of over 5,000 ft. and in $35^{\circ} 45' N.$ and $52^{\circ} 30' E.$ It has a population of 2,500. A cliff on the eastern side of the valley is surmounted by the ruins of an ancient fort popularly ascribed to Alexander the Great.

FISCAL POLICY: *see* FREE TRADE; FAIR TRADE; PROTECTION; TARIFF REFORM; TARIFFS; IMPERIAL PREFERENCE; SAFEGUARDING OF INDUSTRY; CUSTOMS; CUSTOMS HOUSE; CUSTOMS COLLECTOR; CUSTOMS UNION.

FISCAL YEAR, any 12-month period, which may or may not coincide with the calendar year, determined upon by a business or Government as the annual period at the end of which books are closed and the financial condition ascertained. The fiscal year of the British Government closes on April 5, and of the United States Government on June 30.

FISCHART, JOHANN (c. 1545-1591), German satirist and publicist, was born, probably at Strasbourg, about 1545, and was educated at Worms in the house of Kaspar Scheid, whom in the preface to his *Eulenspiegel* he mentions as his "cousin and preceptor." After travelling extensively he returned to take the degree of *doctor iuris* at Basel. From 1575 to 1581 he appears to have been associated in the business of his sister's husband, Bernhard Jobin, the Strasbourg printer. In 1581 Fischart was attached, as advocate to the imperial court of appeal at Spire, and in 1583, when he married, was appointed magistrate at Forbach near Saarbrücken. Here he died in the winter of 1590-91. Fischart wrote under various feigned names, such as Menzer, Reznem, Huldrich Ellposkeros, Jesuwalt Pickhart, Winhold Alkofribas Wüstblutus, Ulrich Mansehr von Treubach and Im Fischen Gilt's Mischen. More than 50 satirical works, both in prose and verse, are ascribed to him, of which the most famous is *Afentheurliche und ungeheuerliche Geschichtschrift vom Leben, Rhaten und Thaten der . . . Helden und Herren Grandgusier Gargantua und Pantagruel* (1575), an imitation of Rabelais, which appeared again in 1577 under the modified title *Naupen-geheuerliche Geschichtsklitterung*.

Fischart had studied not only the ancient literatures, but also those of Italy, France, the Netherlands and England. He was a lawyer, a theologian, a satirist and the most powerful Protestant publicist of the counter-reformation period; in politics he was a republican. Above all, he was a master of language, and was indefatigable with his pen. His satire was levelled mercilessly at all perversities in the public and private life of his time—at astrological superstition, scholastic pedantry, ancestral pride, but especially at the papal dignity and the lives of the priesthood

and the Jesuits. He indulged in the wildest witticisms, the most abandoned caricature; but all with a serious purpose. As a poet, he is characterized by the eloquence and picturesqueness of his style and his symbolical language. Thirty years after Fischart's death his writings, once so popular, were almost entirely forgotten. Recalled to the public attention by Bodmer and Lessing, his position in German literature is now fully assured.

Among Fischart's other works are:—*Von St. Dominici des Prediger-mönchs und St. Francisci Barfüssers arlichem Leben* (1571), a poem with the expressive motto "Ye have noses and smell it not," written to defend the Protestants against certain accusations, one of which was that Luther held communion with the devil; *Eulenspiegel Reimensweis* (written 1571, published 1572); *Aller Praktik Grossmutter* (1572), after Rabelais's *Prognostication Pantagrueline*; *Flöh Hae, Weiber Traz* (1573), in which he describes a battle between fleas and women; *Das glückhafte Schiff von Zürich* (1576, republished 1828, with an introduction by Ludwig Uhland), a delightful poem commemorating the adventure of a company of Zürich arquebusiers, who sailed from their native town to Strasbourg in one day, and brought, as a proof of this feat, a kettleful of *Hirsebrei* (millet), which had been cooked in Zürich, still warm into Strasbourg; *Podagrammisch Trostbüchlein* (1577); *Philosophisch Ehzuchtbüchlein* (1578); the celebrated *Bienenkorb des heiligen römischen Immenschwarms*, etc., a modification of the Dutch *De roomsche Byen-Korf*, by Philipp Marnix of St. Aldegonde, published in 1579 and reprinted in 1847; *Der heilig Brotkorb* (1580), after Calvin's *Traité des reliques*; *Das vierhörne Jesuiterhüttlein*, a rhymed satire against the Jesuits (1580), and a number of smaller poems.

Freiherr von Meusebach, whose valuable collection of Fischart's works has passed into the possession of the royal library in Berlin, deals in his *Fischartstudien* (Halle, 1879) with the great satirist. Fischart's poetical works were published by Hermann Kurz in three volumes (Leipzig, 1866-68); and selections by K. Goedeke (Leipzig, 1800) and by A. Hauffen in Kürschner's *Deutsche Nationalliteratur* (Stuttgart, 1893). *Das glückhafte Schiff* has been frequently reprinted (critical edition by J. Baechtold, 1880). *See* for further biographical details, W. Wackernagel, *Johann Fischart von Strassburg und Basels Anteil an ihm* (2nd ed., Basel, 1875); A. Hauffen, *Johann Fischart* (vol. i., 1921); Leitzmann, *Fischartiana* (1924).

FISCHER, EMIL (1852-1919), German chemist, was born at Euskirchen, Rhenish Prussia, on Oct. 9, 1852. He studied at Bonn and at Strasbourg, where he graduated Ph.D. in 1874. He then acted as assistant to Adolf von Baeyer at Munich for eight years, after which he was appointed to the chair of chemistry successively at Erlangen (1882) and Würzburg (1885). In 1892 he succeeded A. W. von Hofmann as professor of chemistry at Berlin. Emil Fischer devoted himself entirely to organic chemistry, and his investigations are characterized by an originality of idea and readiness of resource which make him the master of this branch of experimental chemistry. The extraordinary merit of his researches was recognized by all the important scientific societies in the world; in 1890 he was awarded the Davy medal of the Royal Society and elected a foreign member in 1899. He was awarded the Nobel prize for chemistry in 1902. Under his control the laboratory at Berlin became one of the most important in existence, and attracted to itself a constant stream of brilliant pupils. Emil Fischer died at Wannsee, Berlin, on July 15, 1919.

In 1875, he published his discovery of the organic derivatives of hydrazine (*q.v.*). He investigated their relation to the diazo compounds (*q.v.*). His observations, published in 1886, that the hydrazones, by treatment with hydrochloric acid or zinc chloride, yielded derivatives of indol, the pyrrol of the benzene series and the parent substance of indigo, were a valuable confirmation of von Baeyer's views on indigo and its derivatives. Of greater moment was his discovery that phenyl hydrazine reacted with the sugars to form substances which he named osazones, and which served to identify such carbohydrates more definitely than had been previously possible. He next turned to the rosaniline dye-stuffs, and in collaboration with his cousin Otto Fischer, he published papers in 1878 and 1879 which established that these dye-stuffs were triphenyl methane derivatives. The results of this work were collected after his death and published as *Untersuchungen über Triphenylmethanfarbstoffe, Hydrazine und Indole* (1924). Fischer's next research was concerned with compounds related to uric acid. Here the ground had been broken, more especially by von Baeyer, but almost all our knowledge of the purine group (*see* PURINES) is due to Fischer. In 1881-82 he established the formulae of uric acid, xanthine, caffeine, theobromine and some

other compounds of this group.

His greatest work was instituted in 1894, when he commenced his great series of papers, wherein the compounds above mentioned were all referred to a nitrogenous base, purine. The base itself was obtained after much difficulty, and an immense series of derivatives were prepared, some of which were patented in view of possible therapeutical applications. These researches were published in a collected form in 1907 with the title *Untersuchungen in der Puringruppe*. When the work on the purine group was progressing satisfactorily he attacked the sugar group. Here again Fischer may be regarded as the prime investigator in this field. His researches may be taken as commencing in 1883; and the results are unparalleled in importance in the history of organic chemistry. The chemical complexity of these carbohydrates (*q.v.*), and the difficulty with which they could be got into a manageable form—they generally appeared as syrups—occasioned much experimental difficulty; but these troubles were little in comparison with the complications due to stereochemical relations. However, Fischer synthesized fructose, glucose and a great number of other sugars, and showed how to distinguish the formulae of the 16 stereoisomeric glucoses (see **STEREOCHEMISTRY** and **ISOMERISM**). The study of the sugars made it necessary to examine the nature, properties and reactions of substances which bring about fermentation (*q.v.*). Fischer attacked the problem presented by ferments and enzymes, and although we as yet know little of this complex subject, to Fischer and his co-worker Abderhalden is due the credit of having laid the foundation of enzyme chemistry (see **ENZYME**). The magnitude of his researches in this field may be gauged by his collected papers, *Untersuchungen über Kohlenhydrate und Fermente* (1909).

From the sugars and ferments it is but a short step to the chemistry of the proteins (*q.v.*). By the introduction of new methods, Fischer succeeded in breaking down the complex proteins into amino-acids and other nitrogenous compounds, the constitutions of most of which have been solved; and by bringing about the recombination of these units, appropriately chosen, he prepared synthetic peptides which approximate to the natural products. His researches made from 1899 to 1906 have been published with the title *Untersuchungen über Aminosäuren, Polypeptides und Proteine* (Berlin, 1907).

Fischer also made a number of investigations on the Walden inversion and on gallic acid derivatives of the sugars which were related to the tannins. During the World War he was very active in organizing German chemical resources. He increased the supply of ammonia available from coke-ovens, encouraged the synthetic nitric acid industry, suggested camphor substitutes and new sources of glycerine. He was particularly concerned with the problem of conserving the food supply.

See Fischer, *Memorial Lecture, Journal of the Chemical Society* (1920).

FISCHER, ERNST KUNO BERTHOLD (1824–1907), German philosopher, was born at Sandewalde, Silesia, on July 23, 1824. Educated at Leipzig and Halle, he became a privat-docent at Heidelberg in 1850, and in 1856 a professor at Jena. In 1872 he succeeded Zeller at Heidelberg as professor of philosophy and of the history of modern German literature. In philosophy, where his attitude was mainly Hegelian, his part was that of an historian and commentator, his chief production being *Gesch. der neuern Phil.* (1852–93). Fischer also made valuable contributions to the study of Kant, Spinoza, Schopenhauer, Bacon, Shakespeare, Goethe, Lessing and Schiller.

The Eng. trans. of his numerous works are: *Francis Bacon*, by J. Oxenford (1857); *Life of Benedict Spinoza*, by F. Schmidt (1882); *A Commentary on Kant's Kritik of Pure Reason*, by J. P. Mahaffy (1866); *Descartes and his School*, by J. P. Gordy (1887); *A Critique of Kant*, by W. S. Hough (1888). See also H. Falkenheim, *Kuno Fischer und die literar-historische Methode* (1892); and bibliography in Baldwin's *Dict. of Philosophy and Psychology* (1905).

FISCHER, THEOBALD (1846–1910), German geographer, was born at Kirchsteitz, Thuringia, on Oct. 31, 1846. He was educated at the universities of Heidelberg and Halle, and visited many parts of Europe in the pursuit of geographical study, but especially the Mediterranean lands, including north Africa (Atlas

lands). The "Mediterranean region" is a conception the world owes to Fischer. His thesis for the rank of *Privatdozent* in the University of Bonn (1876) was entitled *Beiträge zur physischen Geographie der Mittelmeerländer*, and his most important publications are a collection of *Mittelmeerbilder* and his work on the Mediterranean peninsulas of Europe in Kirchhoff's *Allgemeine Länderkunde*. He held professorships of geography at Kiel (1879–83), and at Marburg until his death on Sept. 17, 1910.

FISCHER VON ERLACH, JOHANN BERNHARD (1656–1723), Austrian architect, was born at Graz on July 20, 1656, and died in Vienna on April 5, 1723. He probably began his artistic career as a sculptor. Then, during a period of study in Rome, he turned to architecture, and after his return to Austria in 1683, rose to be one of the most distinguished representatives of the Austrian Baroque. His early work is chiefly connected with Salzburg, where he designed various churches. About 1700 he began his work on the palace and gardens of Schönbrunn—the imperial residence. Other notable works are the royal library, the palace of Prince Eugene, and the church of San Carlo Borromeo in Vienna. He wrote a history of architecture, illustrated with his own engravings, which is one of the first works on this subject. (English ed., *A Plan of Civil and Historical Architecture*, 1730.) His son Josef Emanuel (1693–1742) was also an architect.

See Albert Ilg, *Die Fischer von Erlach* (1895).

FISH, HAMILTON (1808–1893), American statesman, was born in New York city on Aug. 3, 1808. His father, Nicholas Fish (1758–1833), served in the American Revolution. The son graduated at Columbia college in 1827, and in 1830 was admitted to the bar, but practised only a short time. In 1843–45 he was a Whig representative in Congress. He was governor of New York from 1849 to 1851, and was U.S. senator in 1851–57, acting with the Republicans during the last part of his term. In 1861–62 he was associated with John A. Dix, William M. Evarts, William E. Dodge, A. T. Stewart, John Jacob Astor, and other New York men, on the Union defence committee, which (from April 22, 1861, to April 30, 1862) co-operated with the municipal government in the raising and equipping of troops, and disbursed more than \$1,000,000 for the relief of New York volunteers and their families. Fish was secretary of State during President Grant's two Administrations (1869–77). He conducted the negotiations with Great Britain which resulted in the treaty of May 8, 1871, under which the "Alabama claims" were referred to arbitration, and the same disposition was made of the "San Juan boundary dispute," concerning the Oregon boundary line. In 1871 Fish presided at the Peace Conference at Washington between Spain and the allied republics of Peru, Chile, Ecuador and Bolivia, which resulted in the formulation (April 12) of a general truce between those countries, to last indefinitely and not to be broken by any one of them without three years' notice given through the United States; and it was chiefly due to his restraint and moderation that a satisfactory settlement of the "Virginian affair" was reached by the United States and Spain (1873). Fish was vice-president-general of the Society of the Cincinnati in 1848–54, and president-general from 1854 until his death. He died in Garrison, N.Y., on Sept. 7, 1893.

His son, NICHOLAS FISH (1846–1902), was appointed second secretary of legation at Berlin in 1871, became secretary in 1874, was *chargé d'affaires* at Berne in 1877–81, and minister to Belgium in 1882–86, after which he engaged in banking in New York city.

See A. Elwood Canning, *Hamilton Fish* (1918).

FISH, that class of vertebrate animals which lives exclusively in water, breathes through gills, and whose limbs take the form of fins (see **FISHES** and **PISCICULTURE**). The article **FISH-ERIES** deals with the subject from the economic point of view, and **ANGLING** with the sport of fishing. The constellation and sign of the zodiac known as "the fishes" is treated under **PISCES**.

The fish was an early symbol of Christ in primitive and mediaeval Christian art. The origin is to be found in the initial letters of the names and titles of Jesus in Greek, Jesus Christ, Son of God, Saviour, which together spell the Greek word for "fish," *ἰχθῦς*.

FISH COOKERY. The term fish includes many water animals which are classed as "sea food" (e.g., crabs, shrimps, lobsters, turtles, oysters, frogs, etc.), besides fish proper. Fish is sold whole, dressed, salted, dried, tinned or alive. It is generally a cheap and wholesome source of nitrogenous food though compared with meat, bulk for bulk, fish contains more water and refuse. There are three main classes of fish: oily, containing fatty oil dispersed throughout the flesh; white or non-oily (lean), containing oil secreted in the liver; and shell-fish. Examples of oily fish are salmon and herring, flat fish and turbot belong to the lean kinds, while the shell-fish include lobsters, crab, oysters, clams, etc. Owing to the shortness and flakiness of the muscle fibres, fish, with the exception of some shell-fish, is easily digested, and should be eaten with vinegar or some form of acid. Oily fish are more nourishing than lean kinds but less easily digested, and are best grilled or cooked by dry methods. Lean fish are usually supplemented by sauces, etc.

Preparation of Fish for Cooking.—Fresh fish should be "scaled" and cleaned. In skinning round fish, proceed from head to tail, and reverse for flat fish. To fillet flat fish place on a board, grasp the tail firmly with fingers dipped in salt (to prevent slipping), and cut an incision just above the tail. Slip the knife under the flesh and raise it gently, at the same time loosening the skin with the thumb and forefinger of the left hand. Round fish may be baked and stuffed. All trimmings should be placed in a pan and covered with water to make fish stock for sauces. Roes in large fish should be removed, cooked separately and served as savouries on toast.

Methods of Cooking Fish.—There are many ways of cooking fish. Boiling is the simplest, though the least nourishing, as much of the flavouring juices is lost. This method of cooking is suitable for large, round fish or for thick pieces. The water should simmer, not boil, and only enough used to cover the fish. Sea water is excellent for boiling sweet fish. Add lemon juice or vinegar to the water to keep the fish white and firm and add salt unless a salt fish. Boiling is the best method for cooking salt fish. Tasteless fish requires additional spices and flavourings added to the water. Allow 5 min. to the pound for thin fish, 10 min. or over for larger fish. Steaming is better than boiling, but takes a little longer. Small fillets of fish may be steamed on an oiled plate over a pan of boiling water. Squeeze lemon juice over to keep the flesh white. Steaming is useful for invalid fish cookery (see INVALID COOKERY).

Certain fish are best baked and stuffed or baked *au naturel*. Fish may also be baked in a tin with spices and butter, or in milk. Paper bags (oiled) are excellent for baking fish. Truss whole fish before baking. Broiling or grilling is suitable for oily fish, which should be placed on a greased gridiron. If thick, split the fish down the centre and grill the flesh side first. Remove head and tail for grilling. Planked fish is grilled and served on a board made for the purpose. Frying is one of the most popular methods of cooking lean fish and may take the form of frying in a bath of boiling fat or "pan" frying in a shallow pan. Oil is better than any other fat for frying fish, as it keeps the colour a clear golden-brown. All fish that is fried must be perfectly dry. It can be served with a sauce but this is not necessary unless the fish is fried in batter. Certain kinds of fish are tasty if stewed in the form of a *soupy* (in the United States, chowder), that is, slices of fish simmered in broth with vegetables and spices. A *bouillabaisse* is a special dish much eaten on the Continent and consists of a stew or chowder of several kinds of fish. In cooking shell-fish other than crabs and lobsters, be very careful not to boil them, as they then become tough. Periwinkles, snails, etc., are served *au naturel* with butter and chopped parsley. Raw oysters and clams may be served in their shells with accompaniments of vinegar, lemon, red pepper and various other relishes.

Sauces for fish are (a) those with a water white sauce (drawn butter sauce) or a fish stock white sauce as a foundation; (b) those with melted butter as a foundation; (c) those with mayonnaise, Hollandaise or other butter-egg yolk sauces. Sharp ingredients, such as capers, horseradish and pickles, are often added (see SAUCES).

Roe.—This is a spawn or milt of fish. In the case of large fish the roe is removed and prepared for table separately in various ways. Soft roes, as herring, etc., are served on toast as a savoury. Shad roe is a delicacy in the United States. Hard roes, as cod roes, are frequently dipped in batter and fried in deep fat. Caviare, sturgeon roes (salted), is served plain on sippets of bread and butter as *hors d'oeuvres*.

FISH CULTURE: see PISCICULTURE.

FISH CURING, an operation, or series of operations, the object of which is the preservation of the flesh of fish by salting, drying, pickling, or smoking. Though preservation by various means in periods of plenty against periods when fish could not be caught has been practised by man since earliest times, it is only recently that a scientific study of the various processes has been begun and the literature is still of meagre character. Curers, in consequence, rely for results on experience and rule of thumb practices, passed on traditionally from father to son.

The principle involved in salting is one of osmosis, in which a certain amount of salt combines with the water of which the tissues of fish flesh are largely composed. Subsequently the completion of curing may be accomplished by allowing the fish to remain in the salt solution (pickle) of its own creation, as in the case of pickled herrings, sprats, mackerel and salmon; or it may be dried in the sun, or by artificial heat as in the case of salt cod; or smoked, as with red herring.

As civilization has advanced, there has been a tendency in the temperate zones and in regions touched by increasingly rapid transport for the harder cures to be replaced by fresh fish or by more lightly cured preparations, and for the hard cures (cod, ling, saithe or coalfish, haddock) thus superseded to find new markets in less readily accessible parts of the world among more primitive peoples. Thus in the years immediately preceding the World War Germany was taking a steadily increasing volume of fresh herrings but at the same time the quantity being cured was growing because pickled herrings were penetrating further and further into Russia. Similarly, hard cures of cod (also ling, haddock, coalfish and tusk) were being marketed in tropical Africa, Central and South America, experience showing it to be a simpler matter to cure fish in Arctic Norway, at British ports or in Newfoundland for such markets than it is to catch and cure indigenous fish on the spot.

Later developments of the same general tendency have been that with the improvements in refrigeration, cold stored fish begins to compete with cured fish. Of this it is too early to speak, except to state that it has been demonstrated that cold-stored fish can be more widely distributed geographically than was possible with salt cured fish 50 years ago. As a result of improvements in refrigeration at least one fish, the hake, has disappeared from among the kinds which were formerly cured.

Heavy curing of fish was essential in the early days of civilization in northern latitudes when fish flesh had of necessity to take an important place in human fare. With regular supplies of fish available lighter cures have come into use in which the process of smoking is more largely concerned than that of salting. Among these are kippers and bloaters, as split and round herrings are termed respectively, smoked haddock (finnan), whiting and codling. In the case of the last three the fish are headed and split after the manner of cod, except that the backbone is not removed. All these are in popular demand in Great Britain, but in the last few years remarkable developments have followed the introduction of smoked fillets. For the preparation of these boneless strips are cut from such fish as cod, ling, haddock, tusk. Before smoking these are steeped in a pickle to which a harmless vegetable dye (annatto) is customarily added. An economical and readily transported product is then available which has met with a keen demand not only at home but in British colonies.

In Great Britain, the United States, Norway, Holland and Russia cold-smoking is customary, but in Germany and Sweden hot-smoking, by which the fish is partially cooked whilst being smoked, is favoured.

Herrings.—In all matters of smoking the wood used is a question of prime importance. Generally speaking soft resinous woods

are avoided as tending to produce a disagreeable taste. For herrings no wood is equal to oak, though since the War there has been an increasing tendency to dye kippers, with which process many connect the decline of this particular product in the public favour. Of all the fishes subjected to the various curing processes the two kinds taken in the greatest abundance, herring and cod, receive the greatest attention from curers. Reference can be made to innumerable works in many languages dealing with the development of the herring fisheries from earliest times: exact records of the technique of curing fish are less easily come by. And yet the cures of herrings are more diverse than those of any other single species. The average catch yearly by the principal European countries for the period 1910-13 was (in tons) Great Britain 608,000; Norway 271,000; Holland 91,000; Sweden 81,000; Germany 51,000; of which only a very limited proportion reached the consumer in an uncured state. The method of curing most favoured is "pickling," in which the fish in various grades are gutted by removal of the gills and intestines (but not the milt or roe) and packed in layers of salt in water-tight barrels wherein they make their own pickle which ensures preservation. The pre-War European production in this manner was about 4,000,000 barrels annually, three-quarters of which originated in Scotland and England. Conditions in the few years preceding the War were exceptionally favourable for herring production, but as the greatest upheavals resulting from that event took place in the chief herring consuming countries there has been a marked shrinkage in the fishing fleets and catch. The average catch of the principal European nations engaged in the herring fishery was, for the period 1919-23, 496,718 tons, and grave difficulties have been experienced in marketing this reduced amount. Russia, formerly the principal buyer of pickled herrings, is endeavouring to replace requirements by fish of home production, so that it is on Germany, Poland and the Baltic States that curers have to rely to absorb the 2-3 million barrels produced annually. For the Mediterranean countries a dried herring is produced which as "golden" or "silver" cure finds its way to Italy, Greece, Egypt and the Levant, where the dried pilchard, cured only in Cornwall, is marketed.

In the British Isles the curing of herrings is done ashore and a Government brand can be demanded guaranteeing the quality and preparation of the contents of the barrels branded. Dutch, German and French fishermen cure their herrings aboard their ships at sea.

Cod Curing.—Cod, the second most important of the world's food-fishes, are caught off Iceland and the Lofoten islands, in the North sea and on the Atlantic coast of North America. There are two principal cures known as "klipfish" from the practice of spreading the split and salted fish on rocks (*klipper*) to dry and "stockfish" (*stock*, a stick) when the fish are hung up round to dry in the form from which they take their name.

Cod are cured both at sea and ashore, but the final stages of preparation for export are completed ashore. At sea, on the Icelandic fishing grounds in spring, trawlers belonging chiefly to England, Germany and Iceland concentrate on the cod fishery. French trawlers favour more the Newfoundland Banks. When the fish are to be cured at sea they are eviscerated, headed, about two-thirds of the backbone removed, and then thoroughly washed. After this they are stacked in the trawler's hold with salt in plenty between the layers of fish. Sale is by contract or by auction at a price per ton.

It is customary for British vessels proceeding on "salting voyages" to engage Scandinavian "splitters" for the specialized work implied by the word. Machines have recently been devised in Germany which do this work very effectively, and these have also been fitted in ships.

After the fish has been landed at Aberdeen, Hull or Grimsby the process of curing is completed at "cod farms," where the fish are spread on racks exposed to the sun or dried under cover by air heated by coke fires or other means. When the desired standard of dryness has been attained the fish are packed in cases which for some markets are tin lined and hermetically sealed. Large quantities of fish, cleaned at sea and brought ashore in ice in the customary manner of all white fish, are split, salted and dried in

establishments in the manner described above. The curing of ling, coalfish, haddock, tusk, is of minor importance and occurs when these fish are incidental to the cod fishery. Curers of salt fish have constantly to be on their guard against "pink-eye" in their stocks. This is caused by organisms occurring in unsterilized salt which develop under certain conditions of temperature and moisture and, giving the fish a pink appearance, render it unsalable. The chief markets for salt cod are the Roman Catholic countries of Southern Europe (Spain, Portugal, Italy), and of South America (Argentina, Brazil, Uruguay) and the West Indies. The lower grades are also extensively exported to West Africa.

BIBLIOGRAPHY.—"Viking," "The Art of Fish Curing," *Fish Trades Gazette* (1906), a detailed account of the methods employed in Scotland and England; D. K. Tressler, *Marine Products of Commerce* (1923). The results of investigations into various matters affecting fish curing are contained in publications by the following: Director of Fisheries, Bergen; U.S.A. Bureau of Fisheries, Washington; Dept. of Scientific and Industrial Research, London; Fishery Board for Scotland, Edinburgh; Ministry of Agric. and Fisheries, London; Dept. of Agric. and Technical Instruction for Ireland, Dublin; Biological Board for Canada, Ottawa; German Sea Fisheries Society, Berlin; Sea Fisheries Institute, Wesermünde; Imperial Fisheries Institute, Tokyo. FISHER, ANDREW (1862-1928), Australian statesman, was born at Crosshouse, Kilmarnock, Aug. 29, 1862, and began life as a coal miner. He emigrated to Queensland at the age of 23, and was elected to the Queensland legislature in 1893. In 1901 he was elected to the Commonwealth Parliament, joined Mr. Watson's Labour Cabinet of 1904 as Minister of Trade and Customs, and became leader of the Labour party in 1907 on Mr. Watson's resignation. In 1908 he became Prime Minister, but his administration lasted only six months. At the general election in 1910, however, his party was returned with a sweeping majority, and he was Prime Minister for three years, during which period he tackled the question of imperial defence, adopted Lord Kitchener's report of 1909 and passed a measure establishing universal military training. His Ministry fell in 1913, but at the election of Aug. 1914 he was again returned to power and gave Australia a vigorous lead in the early days of the World War. At the end of 1915 he resigned and took up the high commissionership, retiring in 1921 and died in London on Oct. 22, 1928.

FISHER, HERBERT ALBERT LAURENS (1865-), British historian and statesman, was born in London on March 21, 1865. He was educated at Winchester and New college, Oxford, being elected in 1888 to a fellowship at the latter college, where he lectured for some years. In 1911-12 he was appointed Chichele lecturer in modern history at Oxford. He was also a member of the royal commission on the public services of India (1912-15). In 1912 he was appointed vice-chancellor of Sheffield university. In 1916, Fisher became minister of education in Lloyd George's cabinet and was elected to parliament for the Hallam division of Sheffield. In 1918 he was elected Liberal member for the English universities. An Education bill was introduced by him, in Aug. 1917, which contained many important reforms. (See EDUCATION: National Systems, England.) He was a British delegate to the Assembly of the League of Nations (1920-22). In Jan. 1925 he was elected warden of New college, Oxford. He resigned his seat as member for the combined universities in Feb. 1926.

Among his books are *The Mediaeval Empire* (1898); *Studies in Napoleonic Statesmanship* (1903); *A Political History of England* (1906); *Bonapartism* (1908); *Life of F. W. Maitland* (1910); *The Republican Tradition in Europe* (1911); *Political Unions* (1911); *Napoleon Bonaparte* (1913); *The Common Weal* (1924).

FISHER, IRVING (1867-), American economist, was born at Saugerties (N.Y.), Feb. 27, 1867. He studied at Yale, Berlin and Paris. At first he taught mathematics at Yale, but in 1895 was made assistant professor of political economy and in 1898 professor. He was editor of the *Yale Review*, 1896-1910. He served as chairman of many commissions dealing with public health, prohibition and labour. He was an advocate of dollar stabilization (q.v.).

His writings include *Mathematical Investigations in the Theory of Value and Prices* (1892); *A Brief Introduction to the Infinitesimal Calculus* (1897); *The Nature of Capital and Income* (1906); *The*

Purchasing Power of Money (1911); *Stabilizing the Dollar in Purchasing Power* (1919); *America's Interest in World Peace* (1924).

FISHER, JOHN (c. 1469–1535), English cardinal and bishop of Rochester, born at Beverly, went in 1484 to Michael House, Cambridge, where he took his degrees in arts in 1487 and 1491, and, after filling several offices in the university, became master of his college in 1499. He took orders; and his reputation for learning and piety attracted the notice of Margaret Beaufort, mother of Henry VII., who made him her confessor and chaplain. In 1501 he became vice-chancellor; and later on, when chancellor, he was able to forward, if not to initiate, the schemes of his patroness in the foundations of St. John's and Christ's colleges, in addition to two lectureships, in Greek and Hebrew. His love for Cambridge never waned, and his own benefactions took the form of scholarships, fellowships and lectures. In 1503 he was the first Margaret professor at Cambridge; and the following year was raised to the see of Rochester, to which he remained faithful, although the richer sees of Ely and Lincoln were offered to him. He was nominated as one of the English prelates for the Lateran council (1512), but did not attend. A man of strict and simple life, he did not hesitate at the legatine synod of 1517 to censure the clergy, in the presence of Wolsey himself, for their greed of gain and love of display; and in the convocation of 1523 he freely opposed the cardinal's demand for a subsidy for the war in Flanders. A great friend of Erasmus, whom he invited to Cambridge, whilst earnestly working for a reformation of abuses, he had no sympathy with those who attacked doctrine; and he preached at Paul's Cross (May 12, 1521) at the burning of Luther's books. Although he was not the author of Henry's book against Luther, he joined with his friend, Sir Thomas More, in writing a reply to the scurrilous rejoinder made by the reformer. He retained the esteem of the king until the divorce proceedings began in 1527; and then he set himself sternly in favour of the validity of the marriage. He was Queen Catherine's confessor and her only champion and advocate. He appeared on her behalf before the legates at Blackfriars, and wrote a widely read treatise against the divorce.

Recognizing that the true aim of the scheme of church reform brought forward in parliament in 1529 was to put down the only moral force that could withstand the royal will, he energetically opposed the reformation of abuses, which doubtless under other circumstances he would have been the first to accept. In convocation, when the supremacy was discussed (Feb. 11, 1531), he declared that acceptance would cause the clergy "to be hissed out of the society of God's holy Catholic Church"; and it was his influence that brought in the saving clause, *quantum per legem Dei licet*. Through listening to the revelations of the "Holy Maid of Kent," the nun Elizabeth Barton (*q.v.*), he was charged with misprision of treason, and was condemned to the loss of his goods and to imprisonment at the king's will, penalties he was allowed to compound by a fine of £300 (March 25, 1534). Fisher was summoned (April 13) to take the oath prescribed by the Act of Succession, which he was ready to do, were it not that the preamble stated that the offspring of Catherine were illegitimate, and prohibited all faith, trust and obedience to any foreign authority or potentate. Refusing to take the oath, he was committed (April 15) to the Tower, where he suffered greatly from the rigours of a long confinement. On the passing of the Act of Supremacy (Nov. 1534), in which the saving clause of convocation was omitted, he was attainted and deprived of his see. The council, with Thomas Cromwell at their head, visited him on May 7, 1535, and his refusal to acknowledge Henry as supreme head of the church was the ground of his trial. The constancy of Fisher, while driving Henry to a fury that knew no bounds, won the admiration of the whole Christian world, where he had been long known as one of the most learned and pious bishops of the time. Paul III. was unaware of the grave danger in which Fisher lay; and in the hope of reconciling the king with the bishop, created him (May 20, 1535) cardinal priest of St. Vitalis. When the news arrived in England it sealed his fate. Henry, in a rage, declared that if the pope sent Fisher a hat there should be no head for it. The cardinal was brought to trial at Westminster

(June 17, 1535) on the charge that he did "openly declare in English that the king, our sovereign lord, is not supreme head on earth of the Church of England," and was condemned to a traitor's death at Tyburn, a sentence afterwards changed. He was beheaded on Tower Hill on June 22, 1535, after saying the *Te Deum* and the psalm *In te Domine speravi*. His body was buried first at All Hallows, Barking, and then removed to St. Peter's *ad vincula* in the Tower, where it lies beside that of Sir Thomas More. His head was exposed on London Bridge and then thrown into the river. As a champion of the rights of conscience, and as the only one of the English bishops that dared to resist the king's will, Fisher commends himself to all. On Dec. 9, 1886 he was beatified by Leo XIII.

Fisher's Latin works are to be found in the *Opera J. Fisheri quae hactenus inventiri potuerunt omnia* (Würzburg, 1595), and some of his published English works in the Early English Text Society (Extra series, No. 27, part i., 1876). There are others in manuscript at the P.R.O. (27, Henry VIII., No. 887). Besides the State papers, the main sources for his biography are *The Life and Death of that renowned John Fisher, Bishop of Rochester* (London, 1655), by an anonymous writer, the best edition being that of Van Ortroij (Brussels, 1893); Bridgett's *Life of Blessed John Fisher, Bishop of Rochester* (London, 1880 and 1890); and Thureau, *Le bienheureux Jean Fisher* (Paris, 1907). (E. TA.)

FISHER, JOHN ARBUTHNOT FISHER, 1ST BARON (1841–1920), British admiral, was born on Jan. 25, 1841, and entered the navy in June 1854. He served in the Baltic during the Crimean War, and was engaged as midshipman in the "Highflyer," "Chesapeake" and "Furious," in the Chinese War, in the operations required by the occupations of Canton and of the Peiho forts in 1859. He became sub-lieutenant on Jan. 25, 1860, and lieutenant on Nov. 4 of the same year. The cessation of naval wars, at least of wars at sea in which the British navy had to take a part, after 1860, allowed few officers to gain distinction by actual services against the enemy. But they were provided with other ways of proving their ability by the sweeping revolution which transformed the construction, the armament, and the methods of propulsion of all the navies of the world, and with them the once accepted methods of combat. Lieutenant Fisher began his career as a commissioned officer in the year after the launching of the French "Gloire" had set going the long duel in construction between guns and armour. He early made his mark as a student of gunnery, and was promoted commander on Aug. 2, 1869, and captain on Oct. 30, 1874. In this rank he was chosen to serve as president of the committee appointed to revise "The Gunnery Manual of the Fleet." It was his already established reputation which pointed Captain Fisher out for the command of H.M.S. "Inflexible," a vessel which, as the representative of a type, had supplied matter for much discussion. As captain of the "Inflexible" he took part in the bombardment of Alexandria (July 11, 1882). The engagement was not arduous in itself, having been carried out against forts of inferior construction, indifferently armed, and worse garrisoned, but it supplied an opportunity for a display of gunnery, and it was conspicuous in the midst of a long naval peace. The "Inflexible" took a prominent part in the action, and her captain had the command of the naval brigade landed in Alexandria, where he adapted the ironclad train and commanded it in various skirmishes with the enemy. After the Egyptian campaign, he was, in succession, director of Naval Ordnance and Torpedoes (Oct. 1886–May 1891); A.D.C. to Queen Victoria (June 18, 1887–Aug. 2, 1890, at which date he became rear-admiral); admiral superintendent of Portsmouth dockyard (1891–92); a lord commissioner of the navy and comptroller of the navy (1892–97) and vice-admiral (May 8, 1896); commander-in-chief on the North American and West Indian station (1897). In 1899 he acted as naval expert at The Hague Peace Conference, and on July 1, 1899, was appointed commander-in-chief in the Mediterranean. From the Mediterranean command, Admiral Fisher went again to the Admiralty as second sea lord in 1902, and became commander-in-chief at Portsmouth on Aug. 31, 1903, from which post he passed to that of first sea lord. Besides holding the foreign Khedivial and Osmanieh orders, he was created K.C.B. in 1894 and G.C.B. in 1902. As first sea lord, during the years 1903–09, Sir John Fisher had a predomi-

nant influence in all the far-reaching measures of naval development and internal reform; and he was also one of the committee, known as Lord Esher's committee, appointed in 1904 to report on the measures necessary to be taken to put the administration and organization of the British war offices on a sound footing. The changes in naval administration made under him were hotly criticised by his critics, who charged him with autocratic methods, and in 1906-09 with undue subservience to the government's desire for economy; and whatever the efficiency of his own methods at the admiralty, the fact was undeniable that for the first time for very many years the navy suffered, as a service, from the party-spirit which was aroused. It was notorious that Admiral Lord Charles Beresford in particular was acutely hostile to Sir John Fisher's administration; and on his retirement in the spring of 1909 from the position of commander-in-chief of the Channel fleet, Lord Charles put his charges and complaints before the government, and an inquiry was held by a small committee under the Prime Minister. Its report, published in August, was in favour of the Admiralty, though it encouraged the belief that some important suggestions as to the organization of a naval "general staff" would take effect. On Nov. 9 Sir John Fisher was created a peer as Baron Fisher of Kilverstone, Norfolk. He retired from the Admiralty in Jan. 1910.

From 1910 until Oct. 1914 Lord Fisher remained in retirement, although Winston Churchill, then first lord of the Admiralty, constantly consulted him and it was on Fisher's advice that Sir John Jellicoe was designated admiral of the Grand Fleet in the event of war. (It is noteworthy that at the time of the Agadir crisis, Fisher expressed to Lord Esher and others strong disapproval of the War Office plans involving Great Britain in extensive land operations in France.)

Fisher was recalled as first sea lord in place of Prince Louis of Battenberg in the critical days at the end of Oct. 1914. The "Audacious" had been sunk, Cradock heavily defeated off Coronel, German submarines were active and the measure to stop the flow of supplies into Germany were not effective. Fisher took the responsibility of weakening the British fleet in home waters and detached the "Invincible" and "Inflexible" to engage von Spee, with the result that a complete victory was gained in the battle of the Falkland Islands. To Fisher's boldness and realism again were due the new blockade policy and the laying of extensive mine fields. The association between Churchill and Fisher was most happy until it was broken by the Dardanelles enterprise. Fisher never liked it; his preference was for a landing on the coast of Prussia in the Baltic and the employment of Russian troops against the heart of Germany. But he was overpersuaded by Churchill into reluctant acquiescence to the initial efforts against the Dardanelles.

When, however, the first attempt to force the straits had failed, and German submarines had made their appearance in Turkish waters, and it seemed doubtful whether the demands of the French campaign would allow the British to send the necessary reinforcements to the army in Gallipoli, Fisher felt that he could no longer continue to countenance the project of forcing the Dardanelles. At the War council of May 14, 1915 he had declared that "he was against the Dardanelles and had been all along." Churchill afterwards told him that it was not fair to obstruct necessary measures at the Dardanelles and then when things went wrong to turn round and say "I told you so, I was always against it." Fisher replied "I think you are right—it isn't fair." That night Churchill in order to encourage the entry of Italy into the War on the side of the Allies gave instructions that four cruisers should go to the Mediterranean 48 hours before the time arranged, and the minute was signed "First sea lord to see after action." That was the first document seen by Fisher on beginning work as usual at four o'clock next morning. He refused to serve with Churchill any more and resigned. His resignation coinciding with the crisis about high explosive shells, brought down the already shaken Liberal Government, and led to the formation of the first Coalition. The manner of his leaving the Admiralty became Fisher less than anything in his life, but his motives were neither personal nor unworthy. He felt that as

things were he had lost his power of service; that he could only hamper the Dardanelles and be "unfair" to Churchill without influencing events in the direction which he felt was right.

Fisher did useful work later in the War as Chairman of the Inventions board, and when he died on July 10, 1920 and was buried in Westminster Abbey, the crowds felt that they were mourning the greatest British sailor since Nelson. Their reverence was the more remarkable because Fisher never commanded a fleet in action, nor, except the Falkland Islands, is any great victory at sea traceable to his direct inspiration. His enemies accused him of exaggerating the material side of naval power at the expense of the moral and intellectual. He was not good in the logical presentation of an argument; he thought pictorially and the sequence of his ideas expressed themselves in a series of verbal explosions. But his prescience amounted at times almost to second-sight, and he had a genius for the burning phrase that lights up the truth from within. The most amazing quality of the man was that as he grew older he became more radical and revolutionary in his ideas. To the old man in 1919 his own Dreadnought of 13 years was a symbol of effete tradition; his slogan "Sack the lot" was not the prosecution of a personal vendetta against the Admiralty chiefs, but expressed his conviction that though the spirit was eternal, its forms were only made to be broken. He wrote two volumes of memoirs: *Memories* (1919) and *Records* (1919); somewhat scrappy and disorderly in composition but full of his glowing vitality. Fisher married, in 1866, Miss Kate Broughton, by whom he had one son and three daughters. (D. H.; H. SM.)

FISHER (*Mustela pennanti*), a North American member of the weasel family (Mustelidae), black in colour, reaching a total length of about 42 inches, and producing valuable fur. The fisher is also called Pennant's marten, and, by trappers, black cat. (See MARTEN, FUR-BEARING ANIMALS, FUR TRADE.)

FISHERIES. This term as commonly employed embraces every method of pursuit and capture, whether for profit or for sport, of aquatic animals, from whales and seals, which are warm-blooded mammals, to the "tiddlers" prized by urchins. However, neither whaling nor sealing comes within the scope of this article, which is limited to the pursuit of fish properly so-called and is primarily concerned with commercial fisheries for fish for food. Fishing is probably the earliest form of hunting, and, as men were surely hunters before they were cultivators, is actually the oldest industry in the world.

For the most part, the attitude of man towards fisheries has been that of the spendthrift: Nature gave the increase; he had but to use it if he could. The abundance of fishes in their different species varied from year to year, but there was always abundance and it is only in comparatively recent years that serious apprehensions have been entertained lest the operations of man might jeopardize the stability of the stock. The contrary view still finds vigorous expression in some quarters in spite of the rapid growth both of the volume of fishing and of the efficiency and destructiveness of fishing gears.

Most fishes are enormously prolific. A female turbot will produce in one spawning season more than 8,000,000 eggs, a cod 4,500,000, a plaice 300,000, a herring 31,000. The eggs produced by individuals of most of the species of chief importance are numbered at least in hundreds of thousands; but at all stages of their life the fishes are beset by a host of enemies, among whom it is probable that man has been, until recently, the least destructive.

With the growth of the population of the world and the increasing demand upon available resources of food, it has begun to be recognized that man has hitherto failed to take full advantage of the enormous resources of the sea. Approximately three-quarters of the earth's surface is covered by water; but the great fishing-grounds of the world are determined primarily by the depth of water upon them, and are almost entirely within the limit of a depth of 200 fathoms, and chiefly within 100 fathoms. It is improbable that any great abundance of fish is to be found far beyond these limits, and in any case the difficulty and the cost of fishing operations by the methods hitherto in use increase in proportion to the depth of water on the fishing grounds. It is

CHART SHOWING THE TOTAL LANDINGS OF DEMERSAL FISH AND THE NUMBER OF STEAM FISHING VESSELS (EXCLUDING DRIFTERS AFTER 1898) YEARLY SINCE 1886, AND THE AVERAGE CATCH PER DAY'S ABSENCE FROM PORT (C.P.D.A.) MADE BY STEAM TRAWLERS SINCE 1906 (EXCLUDING WAR YEARS)

thus on what may be described as the shelves of the continents or the banks of the oceans that the deep sea fisheries, the chief commercial fisheries of the world, are prosecuted.

Historically speaking, there has been no parallel to the development of the fisheries of the North Atlantic and North Pacific, and more particularly of European waters. Nor must we forget when we speak of the great industrial developments of fisheries in Europe in the past 60 years, and particularly of the ubiquitous steam trawlers of Great Britain, that in the days of the Tudors English fishermen were fishing not only in the North sea and other home waters, but at Iceland, as far east of the North Cape as Vardö, and even off Newfoundland. Throughout the Middle Ages salt fish played a recognised part in the economy of European nations; it was the Lenten fare of Catholic Europe, a regular part of the rations of armies in the field, and the complement of salt meat in the winter food of northern Europe.

In Great Britain today the consumption of fish per head of the population is about 40 lb. annually, and the total consumption of fish is something more than one-third of the total consumption of meat. Fish is also the raw material of various industries; fish-canning, fish-salting, herring-pickling, the manufacture (from the offal of fish) of fish meal, which is a useful feeding stuff for poultry, pigs and cattle, and of fish-manure; and the production of oil of various grades from medicinal cod-liver oil to cruder oils used for such purposes as tanning, soap-making and tempering steel. Glue and isinglass are also among the by-products of fisheries, and attention is now being directed to the conversion of fish-skins into fine leather.

Again, fishing by modern methods provides employment on a large scale in connection with ship-yards, ice-factories, net-factories, motor works, etc. The fishing industry of Great Britain

uses at least 3,000,000 tons of coal a year. The daily transport of fish is an important factor in the activities of some of the principal railway companies. The distribution of fish from the wholesale markets to the retail shops and to the fried fish shops—which handle something like 40 per cent of the total quantity of fish consumed—provides employment for many hands. If account be taken of the many trades and occupations which are in some sort ancillary to or activated, in whole or in part, by the fishing industry, it will be seen that, although the number of fishermen is comparatively small (about 60,000 in Great Britain) the failure of the industry would cause widespread repercussions in the labour market. In every country with a fishing population this would be a calamity; in some, such as Norway and Newfoundland whose leading industry is fishing, it would be a disaster.

But the influence of the fishing industry goes further and deeper than this. It is not generally recognised how great a part fisheries have played in the destinies of nations. A history of fisheries and even of the fisheries of any one country has yet to be written. When the first man ventured to sea in a dug-out, it is probable that his purpose was the better to pursue fish, and not only the deep sea trawlers, liners and drifters of to-day, but the merchant and fighting navies are the lineal descendants of the pre-historic fisherman in his dug-out. Thus fishing may be presumed to have prepared the way for sea trade, without which modern civilisation is inconceivable. The growth of the all-powerful Hanseatic League from the small beginnings of the herring fisheries of Scania, and the rise of the sea-power of the Dutch in the 17th century, following upon their predominance in the fisheries of the North sea, are comparatively modern instances of the influence of fishing on shipping. "It is the fish taken upon his majesty's coasts," wrote Sir William Monson,

admiral of the Narrow Seas, in the reign of James I., "that is the only cause of the increase of shipping in Europe; and he that hath the trade of fishing becomes mightier than all the world besides in the number of ships."

The Tudors in England feared a loss of sea power from the decline of the fisheries which followed the Reformation, and by various measures, including the so-called "political Lent," sought to give a new impetus to the fisheries. The Stuarts with the same object in view sought to assert a British dominion over the North Sea, and it was with the temporary decline of her fishing fleet that in the subsequent struggle with the Dutch, Great Britain encountered perhaps her greatest humiliation at sea. Moreover, throughout the history of Great Britain, the fisheries have not merely been a "nursery" for the mercantile marine and the royal navy but have directly contributed their quota to the fighting forces at sea, and when in the recent World War the fishermen with their ships played a prominent part in combating the menace of mine and submarine, history was repeating itself, as it had from age to age with variations, from the days when the fishermen of the Cinque Ports acquired their privileges in return for naval service.

Fishing Methods and Gears.—The methods of catching swimming fish in use in Great Britain alone are very numerous, and, if one extends one's survey to the whole world, almost innumerable, but all of them are variations of a few radical methods. One, perhaps the earliest, is that of direct attack by means of a spear and is still in use in some parts of the world. The next is a trap devised to intercept and capture roving fish. The various forms of fish-weirs still found here and there on the coasts of Great Britain, which work on the principle of admitting fish on the flood tide and trapping them on the ebb, are probably of primitive origin. From the fish-weir or dam of stone or clay to a similar trap of wattle hedging and thence to fixed nets is a natural logical evolution. Another form of trap is that into which fish are attracted by food, examples of which, probably of primitive origin, are the wickerwork traps used for catching lobsters, prawns and crabs. The baited line was probably first used without a hook, as it is even now in the method of catching eels known as "clotting" or "bobbing," that is tying a bunch of worms at the end of a line, and, when it has been taken by the eel, drawing it swiftly to hand before the eel has had time to disengage its teeth. This method was improved upon by the introduction of a hook, the earliest form of which may have been the thorn hooks still used in parts of Wales and the Thames estuary. From these methods the more elaborate devices employed in commercial fishing to-day have been evolved, the most important development being the device of bringing the trap, in the form of a net, to the fish, instead of trusting to the natural movements of the fish or the lure of bait to bring the fish to a stationary trap.

In the fisheries of the North Atlantic, which are the most highly developed and commercially organised in the world, the methods of fishing of chief importance are trawling, seining, drifting and lining. The first two methods involve the use of a net which is brought to the fish, in the case of the trawl, by dragging on, or near, the bottom of the sea, a bag-shaped net the mouth of which is kept open either by a beam across the head or by the pressure of the water upon wooden kites known as trawl boards attached to the net and, in the case of the seine, by gradually encircling the fish with a net in the centre of which is a bag not unlike that at the end—known as the "cod-end"—of the trawl. The beam trawl is used only on sailing smacks and other small fishing craft; the trawl which depends for its spread on kites is known as the otter trawl and is universally employed on steam trawlers. It is, having regard to all possible circumstances, by far the most efficient instrument for taking "demersal" (*i.e.* bottom-feeding) fish yet devised. One of the most efficient forms of seine net is the instrument chiefly used by the Danish fishermen and adopted to some extent in recent years by the British fishing industry.

The principle of the drift net differs from that of the trawl and of the seine in that it is not actively approached to the fish. On the other hand, it differs from the stationary trap and the many

forms of stationary net in that it is attached either to a floating buoy or to a drifting ship (hence the name) and moves with the buoy or ship under the influence of wind and tide. It is lightly and strongly made of cotton and is the instrument principally used in the great herring fisheries. Each herring net measures from 50–60 yards long and about 14 yards deep, but the nets are used in "fleets," as many as 85 or more of them being employed at one time from one vessel so as to form an extended wall of netting hanging perpendicularly in the water. The net is generally fished about 3 yards below the surface of the water, being kept at the right level by a series of buoys or "pellets" connected with the head-line by strops. This net is devised to intercept sizeable fish which in the attempt to pass it are caught by the gills. Drift nets of various dimensions are used for catching "pelagic" fish, that is to say, fish that swim in the upper layers of the water, chiefly herring, mackerel, pilchards and sprats. Drift nets of larger mesh are also used for catching salmon.

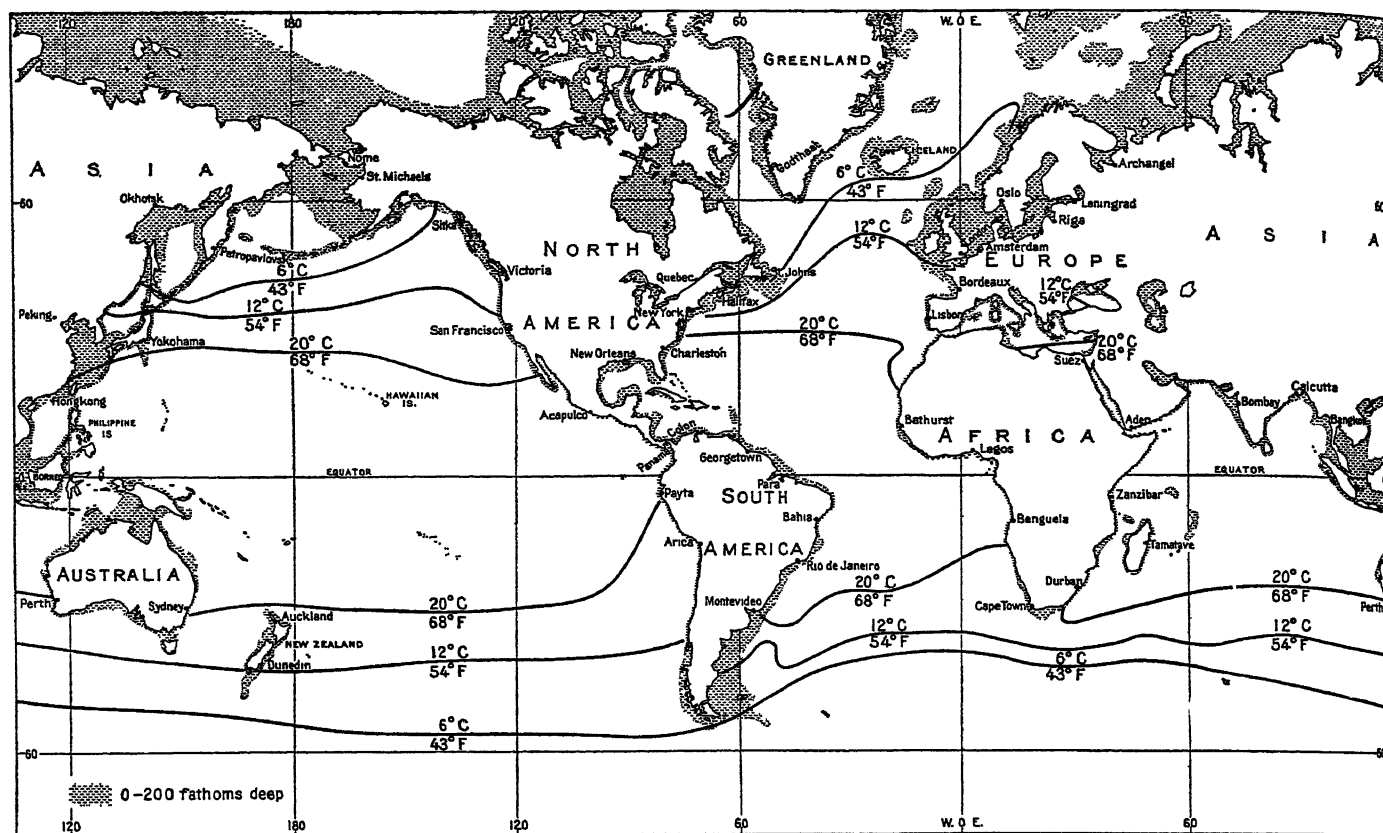

Fishing by means of lines with baited hooks was formerly of much greater commercial importance than it is to-day. There are two methods of lining, hand-lining and long-lining. In the former method the line is drawn by hand as soon as the fish is felt; in the latter, the line is shot and left unattended till it is time to haul. Hand-lines are not, generally speaking, of great commercial importance. A long line is fitted with a great number of hooks attached to the main line by thin strong lines of materials which vary according to the character of the fish and to local custom. Long-lines may be set at low water on the sands, but more often they are worked from fishing vessels in deep water. All the deep water lines are anchored and buoyed at each end, the longer ones also anchored and buoyed at intervals along the whole length. On a large steam liner the number of hooks on one line may be anything from 1,000 to 5,500. Deep-sea long lines are chiefly used for cod and halibut. The baits vary according to local conditions, and include mussels, whelks, squid and herrings.

TRADE ASPECTS

World Fisheries.—The pursuit of fish is, in greater or less degree, world-wide. No estimate of the output of the fisheries of the world can be wholly reliable, or indeed, more than an approximation, because in many parts of the world where fishing is actively carried on no statistics are compiled. Again, the countries which do publish statistics do not compile them on a uniform plan, and it is generally difficult to derive from them comparable figures. Most of the countries of Europe, however, the United States of America, the British dominions and Japan publish annual statistics of some sort or another, and a comprehensive statistical account of the greater part of the Fisheries of Europe will be found in the *Bulletin Statistique des Pêches Maritimes* of the International Council for the Exploration of the Sea.

A further difficulty arises from the fact that, although, in many parts of the world, the inland fisheries are of great economic importance, statistics of their yield are usually lacking. Here, however, attention will be concentrated chiefly on the sea fisheries which are the most highly developed and organized, particularly in the northern hemisphere. The available statistics, excluding as far as possible the products of inland fisheries and those products of the sea outside the category of food-fishes, *e.g.*, seals, whales, corals, sponges, etc., show an output of food-fish to the value of more than £109,000,000 sterling per annum. This figure does not include the fisheries of—in Europe—Italy, Russia, Greece and Turkey; with the exception of Japan it omits practically the whole of the Orient; nor does it include South and Central America, the West Indies, the greater part of Africa and the islands of the south Pacific and south Atlantic.

In Europe, Great Britain easily leads the way in sea fisheries, with an output (1925) valued at over £20,250,000. France comes next with, in round figures, £7,000,000 worth; Norway next with £4,850,000 worth; then Spain with £4,000,000 worth. On the American continent the value of the catch of the U.S.A. is over £19,000,000, that of Canada over £5,000,000, that of Newfoundland, with Labrador, over £2,000,000. The only other British dominion with landings worth more than one million pounds is the

FROM THE REPORT OF THE IMPERIAL ECONOMIC COMMITTEE, PART V—FISH

MAP OF THE WORLD WITH THE AREA WITHIN 200 FATHOM LINE STIPPLED SHOWING THE LOCATIONS OF THE PRINCIPAL FISHING GROUNDS, AND THE MEAN ANNUAL ISOTHERMS INDICATING THE DISTRIBUTION OF THE KINDS OF FISH

commonwealth of Australia, with £1,200,000 worth. The most startling outcome of a study of all the statistics available is that in respect of the value of its landings of sea fish Japan is the foremost fishing country of the world, with landings valued at more than £30,600,000.

Fish is a very important, indeed a necessary item in the diet of rice-eating populations. If one considers of how great a part of the population of the Far East rice is the staple food, one can appreciate the importance of the part played by fisheries in the economy of the eastern nations. In Japan sea fisheries predominate; but in British India, although in certain provinces, notably on the west coast of Madras, serious and not unsuccessful attempts have been made to develop the sea fisheries, the economic importance of the inland fisheries is probably greater. In Malaya and in Ceylon the sea fisheries are actively exploited. In many parts of Africa fish is greatly sought after by the native population. Indeed, if one could procure an account of the total catch of fish—both sea fish and freshwater fish—throughout the world, the value would certainly reach a startling figure. In Tressler's *Marine Products of Commerce* the annual value of fish and fishery products is placed approximately at \$800,000,000, say £160,000,000. This is probably too conservative an estimate.

Shellfish.—The term "shellfish" embraces the edible species of both crustaceans (crabs, lobsters, crawfish, prawns and shrimps) and molluscs (oysters, mussels, cockles, scallops, clams, whelks, etc.). Their economic importance varies from country to country, but is nowhere comparable with that of the fisheries for what are commonly known as "wet fish." For instance, in Great Britain the total value of all shellfish (1926) was £599,817, but in the United States of America the annual first value of the crop of oysters is about £2,500,000, the value of the output in 1922 of canned oysters was about £480,000, and that of shell-grit, a by-product of the oyster fisheries, of which great quantities are exported to Great Britain and elsewhere for feeding to laying hens, about £400,000 (*see OYSTER*). Lobsters are an important article of commerce in Canada, whence Great Britain alone imports canned lobsters to the value of about

£400,000 per annum. Japan has a considerable and developing trade in canned crab meat and South Africa in canned crawfish.

The yearly value of the lobster fisheries of Great Britain is £115,000 and of the crab fisheries £96,000; and it is interesting to observe that the shrimp fisheries reach an annual value of between £80,000 and £90,000. The most prolific of the fisheries for molluscs are the cockle and mussel fisheries, in that order. The potential output of the mussel fisheries of Great Britain is practically unlimited; but many of the most prolific beds have been closed owing to sewage pollution. Mussels, though themselves immune, are capable of transmitting typhoid and other intestinal diseases, whence arises the necessity for closing mussel fisheries in heavily polluted areas. Methods have recently been elaborated in Great Britain by the Ministry of Agriculture and Fisheries by which polluted mussels can be effectively and economically cleansed. The chief importance of the shellfish fisheries of Great Britain lies in the fact that they contribute to the livelihood of the declining population of inshore fishermen.

BRITISH FISHERIES

It is worth while in a study of fisheries to consider the British fisheries in some detail because they are, so far as sea-fishing is concerned, the most highly organised in the world, with the possible exception of those of Japan. The inland fisheries of Great Britain are of little commercial significance. The salmon fisheries are exploited commercially, and have thus a certain importance, but reliable statistics of the catch of salmon in the British Isles are not available. The salmon fisheries of many of the rivers of Great Britain have suffered from reckless pollution. At their best they could not bear comparison in the commercial sense with those of the western rivers of North America which provide, in the various breeds of Pacific salmon, the raw material of a great canning industry and trade. The value of the trout and freshwater fisheries of Great Britain is almost wholly recreative.

It is as a deep-sea fishing nation that Great Britain is supreme, for no country has so great a fleet of powerful steam vessels

equipped for distant voyages. Although some progress has lately been made in the use of the internal combustion engine for fishing vessels of the larger deep-sea types, steam is still the chief index of power and the following comparative table is, therefore, of interest:

The Number of Steam Fishing Vessels Employed by Certain Countries of Europe, 1925

Great Britain	Germany	France	Norway	Holland
3,020	465	456	366	228

The steam-fishing vessels of Great Britain are chiefly trawlers and drifters, of which those with the widest range of fishing are steam trawlers. The following table affords an index of comparative steam trawling power:

The Number of Steam Trawlers Employed by Certain Countries of Europe, 1925

Great Britain	France	Germany	Holland	Sweden
1,563	430* (year 1927)	393	167	45

*This number includes 37 trawlers of more than 500 tons employed in the Newfoundland fisheries, six of which are actually over 1,000 tons.

Of the British steam trawlers, 1,222 fish from ports of England and Wales, visiting the fishing grounds of the whole of the Continental Shelf, from Iceland to Morocco and from the Barentz sea to the west of Scotland, Rockall and the south west of Ireland.

The steam trawlers built in Great Britain during and since the World War conform fairly closely to three types which are distinguished as the "Mersey," "Castle" and "Strath" types. They are all steel built. The following table gives their usual dimensions:

Type	Length	Beam	Depth	Gross tonnage
<i>Trawler:</i>				
"Mersey"	138'	23.7'	13.5'	324
"Castle"	125'	23.6'	12.7'	275
"Strath"	115'	22'	13'	215

The "Mersey" type is that generally used for fishing in Icelandic and Murman coast waters; the "Castle" for the hake fishery along the Atlantic Slope; the "Strath" for the North sea. The tendency is for the size and power of the steam trawlers used for the more distant voyages to increase.

Of the drifters some are still built of wood, but the majority of steel. The usual dimensions of drifters are as follows:

Type	Length	Beam	Depth	Gross tonnage
Drifter	85.8'	18.6'	9.2'	95

A certain number of vessels are used alternatively for either drifting or trawling.

The relative importance of the different methods of fishing in Great Britain may be gauged by reference to the following figures:

Quantity of Wet Fish of British Taking Landed in Great Britain in 1926 by Each Method of Capture

Trawl	Drift	Lines	Danish Seine
Cwt. 9,481,000	Cwt. 7,853,000	Cwt. 993,000	Cwt. 353,000

In addition 286,000 cwt. were taken by other or unstated methods. Of the total, 18,965,000 cwt., 16,089,000 cwt. were taken by vessels fishing under steam power, although the coal

supply was curtailed by the strike of that year. Trawlers, liners and seiners take chiefly demersal fish (known to the trade as "white" fish), i.e., fish normally found feeding at the bottom of the sea, but some mackerel are taken by the trawl and seine, and there has been an important development in recent years of trawling for herring. For a few years before the war this method of fishing for herring was actively practised at certain times and places by British vessels and is still used at the Smalls, but since the war it has been most highly developed by Germany. The relative values of the demersal and pelagic fisheries may be gauged by reference to the following figures:

Quantity and Value of Demersal and Pelagic Fish of British Taking Landed in Great Britain in 1926

Demersal		Pelagic (Chiefly Herring)	
Quantity	Value	Quantity	Value
Cwt.	£	Cwt.	£
10,961,000	13,541,000	8,000,000	3,503,000

In considering these figures, regard must be had to the fact that since the war the herring fisheries, which depend for the most part upon the export trade in cured herrings, have suffered seriously from the disorganisation of the markets of Europe, and particularly the markets of pre-war Russia, which country formerly absorbed more than 50% of the export. The white fish fisheries, on the other hand, which depend mainly upon the home market for fresh fish have not been affected by post-war conditions to the same extent. The effects of the change may in part be gauged by reference to corresponding figures for the year 1913:—

Quantity and Value of Demersal and Pelagic Fish of British Taking Landed in Great Britain in 1913

Demersal		Pelagic (Chiefly Herring)	
Quantity	Value	Quantity	Value
Cwt.	£	Cwt.	£
11,096,000	9,096,000	12,317,000	4,633,000

Although steam trawling is the predominant method of fishing for demersal fish in England and Wales, new methods are always being tried. The use of the Danish seine is a comparative novelty. This instrument is worked by the Danes from motor boats of comparatively small size, but, by their British imitators, mainly from steam vessels of the drifter type. There have been developments also of trawling in the direction of the improved efficiency of the trawl itself. A more recent enterprise which may be the precursor of more important developments is the commissioning by a well-known firm of trawler owners of two vessels of over 3,500 and 10,000 gross tons, respectively, to exploit the waters west of Greenland. These vessels carry a large number of Norwegian dories, which fish by line, bringing back their catches to the parent ships. The fish caught is in part sent by steam trawlers, acting as carriers, to England for immediate sale, and part of it is frozen and stored on board for future use. There is also machinery on board for the extraction of oil from the livers of fish, and for the turning of offal into fish meal; so that, in effect, the parent ships are also floating factories. If this method stands the test of experience, the enterprise may be the forerunner of developments of a revolutionary character. Trawlers did excellent work in the World War when they were employed principally on mine-sweeping service, usually armed with a light gun and a rifle or two.

There has been, especially since the introduction of steam power in the fishing industry, a growing tendency in Great Britain towards the centralization and industrialization of fisheries. The following table indicates the relative importance of the major fishing ports in which the commercial fisheries are chiefly concentrated (of the Scottish ports, Aberdeen and Granton alone are largely devoted to steam trawling; of the rest the herring fisheries supply the bulk of the catch, as is also the case of Yarmouth and Lowestoft among the English ports):

Average Daily Landings of Wet Fish at Ports at Which the Quantity Landed Daily Was 20 Tons or Over in Either of the Years 1913 and 1926

Port	1913	1926	
	British	British	Foreign
	Tons	Tons	Tons
Grimsby	584	493	69
Hull	262	383	29
Aberdeen	263	243	153
Yarmouth	512	246	..
Lowestoft	397	224	3
Fleetwood	121	147	9
Lerwick	101	121	..
Milford Haven	80	103	3
Shields, North	150	83	..
Wick	68	82	..
Stornoway	88	73	..
Peterhead	131	72	..
Fraserburgh	109	69	..
London	157	56	..
Granton	50	56	..
Stronsay	45	47	..
Newlyn	18	38	..
Swansea	25	33	..
Hartlepool	41	32	..
Plymouth	14	32	..
Cardiff	22	27	..
Scarborough	27	14	..
Blyth	36
All ports	3,301*	2,674	266

*In 1913 the total daily landings by foreign vessels direct from the fishing grounds was 120 tons.

From a general economic point of view this centralization has advantages, but it has had a regrettable sequel in the depression of the smaller fishing ports, which have been unable to withstand the competition of their more powerful and better organized rivals. Their contribution to the fish supply of the country is, in these days, no more than 5% of the total—but they have played a great part as a “nursery” of natural seamen for the mercantile marine and the royal navy and have been the chief source of strength of the life-boat service. With the centralization of the fisheries and the development of the steam trawler, by means of which a smaller number of men can catch a greater quantity of fish, the number of fishermen regularly employed has declined. This fact must be reckoned a misfortune to an island nation, the heart of a great empire dependent for its existence on the freedom of the seas and, therefore, on an adequate supply of seamen to sail and to defend the sea routes.

FISHERIES OF THE BRITISH EMPIRE

Reference has been made to some fisheries of the British empire. If a chart of the world be studied with special reference to the sea areas within the depth of 200 fathoms—that being roughly the limit of depth of the fishing grounds—it will be seen that most of the principal fishing grounds are fairly easily accessible from different parts of the British empire. In Canada and Newfoundland there are already well-established fishing industries exploiting the fisheries of the north-western Atlantic, and an experimental station has recently been erected at Halifax under the control of the Marine Biological board for the study of the preservation of fish by brine freezing, with a view to the development of an export trade to Europe. Canada also, and particularly British Columbia, exploits the fisheries of the north Pacific, the most important fisheries being those for salmon (which accounts for something more than three-quarters of the annual value of the fisheries of British Columbia), halibut and herring.

Comparatively little attention has until recently been bestowed upon the fisheries of Australia, and the fishing grounds have only been partially explored. The lack of interest in fisheries may be accounted for partly by difficulties of transport and partly by the relative cheapness of meat. There are, beyond doubt, large areas of trawlable water round the coasts, and there is every reason to believe that they are prolific of fish. In recent years a trawling industry has grown up in New South Wales, and the Australian Development Commission is now seriously studying the question

of the development of Australian fisheries.

The fisheries of New Zealand are already well developed and steadily increase in importance. Between 40 and 50 steam trawlers are employed and about 1,300 vessels of smaller types. Oysters of high quality are produced, particularly in Foveaux strait, and the endeavour is being made to acclimatize turbot and other food fishes from the north Atlantic.

It is probable that the most important development in the near future in British empire fisheries will take place in South Africa, where surveys already carried out and at present in progress have revealed rich and extensive fishing grounds, some within a few hours steaming of Cape Town, others at no great distance from Durban. A fishing harbours committee was appointed in Oct. 1925, by the Union Government to investigate and report on the improvement of the harbours along the coast and of the assistance which could be given to encourage fishing industries. A small trawling industry has already been developed, with Cape Town, and though South Africa imports considerable quantities of cured, dried and preserved fish, its export trade in fish amounts already to some £300,000 worth a year and is growing steadily. The chief item of export is preserved crawfish, valued at over £200,000 a year, the principal market for which is in France. Fresh and frozen fish are exported chiefly to Australia. There is also a considerable market for fresh fish in South Africa, particularly in the towns of Rand.

The fisheries of the tropical regions of the empire stand on a different footing to those hitherto mentioned. It is probable that in the warmer seas there is a greater number of species of fish, but that there are no such great concentrations of any one species as are found in the colder regions; moreover, the areas within the 200 fathom line are on the whole less extensive in the tropics than in the northern seas, but fishing is carried on on practically all the shores of the tropical colonies and of India. On the west coast of Madras, where the fisheries are more systematically organised than in other parts of the province and statistics are collected, some 54,000 tons of fish are landed annually, valued at between £400,000 and £500,000. Statistics are not available for the fisheries of the east coast of the province. On the coast of Bombay fishing by old-fashioned methods is carried on and attempts have recently been made to develop trawling, hitherto with little success. The fisheries of Bengal supply to Calcutta alone about 16,000 tons of fish yearly. In Ceylon and in Malaya experimental work is being conducted by the Governments with a view to the development on more modern lines of age-old fishing industries.

Generally speaking, it may be said that throughout the empire there has developed in the present century a disposition to pay greater attention than heretofore to the food resources of the sea, and that this disposition has been translated into active energy.

UNITED STATES FISHERIES

The United States fisheries supporting a large manufacturing trade are prosecuted on the seaboard of the Atlantic and Pacific oceans, in the Great Lakes and in many prolific rivers. Their range extends from Alaska south-eastwards to Florida and over something more than 100° of longitude. Although in respect neither of latitude nor of longitude is their range much greater than that covered by the ubiquitous steam trawlers of Great Britain, their variety is so great that no summary account can do justice to it. For details, reference must be made to the reports of the individual States and of the bureau of fisheries, which is attached to the Department of Commerce.

The value and importance of the industry increases steadily with growing recognition and increasing demand; but there is as yet a lack of such detailed and comprehensive statistics as are essential to an accurate economic survey of the industry. The importance of such statistics is, however, now fully recognized: it was emphasised again and again at a conference of the division of scientific inquiry organised in Jan., 1927, by the bureau of fisheries, and great progress has been made in recent years through the efforts of the bureau to make good the deficiency.

It is calculated that the fisheries and fishery industries of the

United States (including whale, sponge and other fisheries, which it is difficult to extract) employ about 190,000 persons, and that the property and equipment involved in them is worth more than \$210,000,000. The quantity of fishery products sold by fishermen is over 1,300,000 tons, valued at nearly \$109,000,000. Of the manufactured fish products the most important are:

(1) Canned products, over \$86,000,000 worth, the chief of which are salmon, over \$56,000,000 worth, and sardines, about \$14,500,000.

(2) Fish oils, 10,900,000 gallons, valued at something more than \$5,000,000. Of these, the most important are menhaden, about 4,000,000 gallons; herring, over 3,000,000 gallons, and sardine, over 2,000,000 gallons.

(3) Fish meal, about 93,000 tons, valued at about \$3,650,000.

(4) Fish glue, 520,600 gallons, valued at about \$732,000.

(5) Poultry grit, about 251,000 tons, valued at \$2,400,000.

The most important sea fisheries are those centred on the three ports of Boston and Gloucester, Mass., and Portland, Me. These fisheries employ 350 sail, steam and oil-driven vessels, including 30 steam trawlers. The aggregate landings of the three ports are about 106,500 tons and their value over \$9,000,000. The three most important fishes are haddock, about 42,000 tons; cod, about 35,000 tons; and mackerel, about 16,000 tons. In 1926, the year to which the above figures belong, about 26% of the catch was taken by steam trawlers; again, 83% was taken off the coast of the United States, 16% off that of Canada, and 1% on the banks of Newfoundland.

It is said that over 90% of the sea fish landed in American ports is consumed within 200 miles of the coast. It is, however, generally anticipated that, as the result of the improvement of methods of transport, by means of which it is hoped to bring sea fish within reach of consumers far inland, there will, in the near future, be a great development of sea fishing, and especially of trawling. The tendency at present is to rely mainly on vessels of comparatively small tonnage—not more than 100 tons—using oil engines of diesel or semi-diesel type. If the development of the markets is as great as is expected in some quarters, it seems probable that steam trawling may also develop.

The lobster fisheries, which have long suffered from the results of indiscreet exploitation, are still one of the important branches of the fishing industry of the New England States and particularly of the State of Maine.

The first value of the fisheries of the States of the Pacific Coast is (figures based on statistics for 1925) about \$24,500,000. The landings of fish, other than shell-fish, are about 266,000 tons, and of shellfish about 5,600 tons. By far the most valuable fishery is that for salmon, yielding over 62,000 tons, with a value of over \$10,000,000. Next in importance is the tuna fishery of some 24,000 tons, with a value of about \$4,500,000. The halibut fishery, centred at Seattle but prosecuted from California northward, is next in importance. The landings amount to between 8,000 and 9,000 tons, and the value to about \$2,177,000. These figures do not include something over 1,000 tons landed in Alaska. The sardine fisheries, valued at about \$2,000,000 are fourth in importance, though the yield of these fisheries, about 140,000 tons, is greatly in excess of all the rest.

The oyster fisheries of the United States exceed by a considerable margin those of the rest of the world. The chief producing States are Maryland and Virginia. Maryland, in 1880, the highest recorded year, produced over 10,000,000 bushels, valued at 5 million dollars, and, in 1915, the lowest recorded year, over 4,000,000 bushels, valued at 3½ million dollars. The output of Virginia in 1925 was 4,300,000 bushels, valued at over 2½ million dollars. The highest previous record of this State (1904) was 7,600,000 bushels, valued at more than 3½ million dollars. Other States producing over 1,000,000 bushels annually are New York, New Jersey, Mississippi and Louisiana.

The fisheries of the Great Lakes are shared between the United States and Canada, the catch of the former being about double that of the latter. The United States landings from the lakes in 1925 amounted to nearly 31,000 tons; in the highest recorded year, 1915, the landings exceeded 48,000 tons. Over 4,500 tons of

lake trout were landed in 1925, of which more than 3,000 tons came from Lake Michigan. The landings of white fish (*Coregonus clupeiformis*) were 1,500 tons, chiefly from lakes Michigan and Huron. The heaviest landings were those of lake herring, 6,500 tons, of which about 60% was taken in Lake Superior and nearly 30% from Lake Michigan. Blue pike, 4,700 tons, are taken almost exclusively in Lake Erie. Sturgeon have varied between 48 tons in 1915 and 11 tons in 1925.

The most important anadromous fishes, other than salmon, are shad, alewives and striped bass. The shad fisheries of the Potomac yielded in 1926 over 460 tons, valued at \$217,000, and, in 1922, the highest previously recorded year, nearly 1,400 tons. The landings from the Hudson river are, roughly, a quarter of those of the Potomac. The landings of alewives from the Potomac (1926) were 2,500 tons, valued at \$55,000. In the highest previously recorded year (1909) these landings were more than doubled.

The striped bass is fished all along the Atlantic coast of the States, and, like the shad, has been successfully naturalized on the Pacific coast.

The administration of the fisheries is in the hands of the various States, but the bureau of fisheries at Washington, which is attached to the Department of Commerce, not only conducts scientific investigations, either independently or in co-operation with provincial investigators, but has acted as a clearing-house for statistical information collected within the States, largely at its instigation. Only the State Governments have authority to enforce the collection of statistical records, and the function of the bureau is, in this respect, chiefly one of advice, co-ordination and compilation. It is through the bureau also that the United States is represented in the North American Committee of Fishery Investigations. The bureau publishes annual reports on the fishing industries of the United States, including steadily improving statistical material, and *Reports on the Progress of Biological Studies*, which give a general picture of investigations conducted and of their results. Nor are the investigations of the bureau confined to purely biological studies. They embrace important investigations of the technique of handling fish after capture, and the bureau has played an important part in the recent development of the "package fish" trade.

The attention of the bureau has also been directed to improving the method of production of such fishery products as oil, meal and manure, with a view to eliminating waste, more especially in connection with the menhaden industry and with the disposal of the waste from filleting and canning. The investigations of the bureau embrace also such subjects as the preservation of nets, the canning of sardines and inquiries as to the nutritive value of fish.

PISCICULTURE

The prospect of very considerably increasing by artificial means the stocks of those multitudinous fishes which are the foundation of the great commercial fisheries of to-day is at present remote. There is no reason to discourage researches directed to the artificial propagation of fish of every kind, but for the present the more practical line of inquiry will be that which aims rather at the prevention of wasteful exploitation than at artificial contributions to the stock.

Certain fishes lend themselves to the art of pisciculture, more or less according to circumstances. Among freshwater fishes those of the carp family can be successfully bred and reared in captivity, and trout can be profitably hatched in special receptacles and reared in suitable ponds to the yearling or two-year-old stage, or even further, to be disposed of either for stocking or restocking sporting waters or for consumption in hotels and restaurants. The process is comparatively simple. Usually the ripe female fish are "stripped," the eggs being allowed to fall into a vessel of water into which a little milt from the male is introduced, the eggs thus fertilized being then transferred to the hatching receptacles. The same process can be applied to sea fishes, and experiments have been carried out in the distribution of newly hatched larvae of plaice and cod in waters where it is desired to increase the stock; but there is no convincing evidence in the case of these

fishes that the result sought has in any case been achieved. The great fecundity of sea fishes is nature's provision against an enormously high rate of mortality, and the number of larvae which it is practicable to hatch in a hatchery of reasonable size is so small by comparison with the natural distribution that it is inherently improbable that the output of a hatchery could make an appreciable difference in the abundance of the stock. The investigations undertaken by Captain Dannevig in selected Norwegian fjords in 1904 and 1905 tend to confirm this conclusion. (See *Report for 1906 of the Lancashire Sea-fisheries Laboratory*, Liverpool, 1907.) A possible exception may be found in the results of the work of the Commission on Inland Fisheries in the artificial rearing of young lobsters from the egg to the lobsterling stage in the quiet waters of Rhode Island, U.S.A. There appears to be some evidence of improvement of the lobster fisheries resulting from this work, but whether the improvement is to be attributed to this cause or to such methods of conservation as, e.g., protection of the berried female, and whether in the former case the improvement has been proportionate to the cost involved, is open to some doubt. (See *Annual Reports of the Commissioners of Inland Fisheries, Rhode Island*, especially those for 1908 [Special paper by A. O. Mead] and 1910 [Appendix].)

Artificial methods of cultivation have chiefly proved useful where it has been desired to populate streams or parts of streams which are understocked, or to introduce into a river a new species of fish. The distribution of eyed ova or of yearling fry of trout or salmon in waters inaccessible to native fish may lead to the establishment of a stock or to the increase of the total run of salmon in a river. The shad has been successfully acclimatized in the rivers of California and in the Mississippi by the distribution of artificially propagated eggs from the eastern rivers of the United States. The quinnat and Atlantic salmon and the brown and rainbow trout have by similar means been successfully naturalized in the rivers of New Zealand. Experiments which have been carried out in certain British rivers for the purpose of improving the native stock of salmon by the introduction of fresh blood by crossing with the stock of other rivers by means of artificial fertilization of the eggs have hitherto been inconclusive.

There is another branch of pisciculture which may be broadly summed up as transplantation. This method is familiar to every oyster planter and is usefully employed in the cultivation of other molluscs, such as cockles, mussels, etc. The main purposes of transplantation of molluscs are to relieve over-crowding of young fish and to place the mature fish on beds where the conditions are suitable for fattening. Transplantation is an essential feature of successful oyster farming (see OYSTER).

Successful results have attended the transplantation of eels. Millions of elvers are annually captured in the river Severn and exported to Germany for distribution in suitable waters in that country. Similarly elvers are trapped in the Danish fjords and transplanted to suitable lagoons to become the source of a profitable industry.

Reference is made below to the rapid growth of plaice transplanted from the eastern waters of the North Sea to the Dogger Bank, and similar experiments in the transplantation of plaice from the outer lagoons of the Limfjord in Denmark to the inner, which are rich in food but are blocked against the immigration of flat fish by dense growths of sea grass (*Zostera*), have laid the foundations of a profitable fishery in these waters.

So far as experience goes, then, it is clear that attempts to increase the supply of sea fish by artificial hatching have been unsuccessful, that the increase of the stock by transplantation succeeds in the case of molluscs and in the case of flat fish in special circumstances, such as those appertaining in the Danish fjords, and may prove successful with certain fishes in more open waters. Artificial propagation from the egg is useful for the introduction of a new stock of fish in suitable river waters either by the distribution of eyed ova or, where that is impracticable, by the distribution of young fish which have reached an age at which they can take care of themselves. It is extremely doubtful whether it is ever worth while to distribute the newly hatched larvae, which are very delicate and are exposed on distribution

in the open waters of a stream or of the sea to a thousand hazards.

Scientific Research.—Speaking of the inaugural meeting of the International Fisheries Exhibition of 1883, T. H. Huxley said, "I believe that the cod fishery, the herring fishery, the pilchard fishery, the mackerel fishery, and probably all the great sea-fisheries are inexhaustible; that is to say that nothing we do seriously affects the number of fish." In an earlier passage of his argument, which was, in effect, that the fish were so prodigiously numerous and the quantity caught by man so insignificant by comparison with the other destructive agencies at work that regulation of man's operations would be futile, he qualified his conclusion with the words, "in relation to our present method of fishing." In 1883 the use of steam power for fishing was hardly regarded seriously (the first experiment was made in 1877 with an old paddle tug out of North Shields), the otter trawl had not been invented, and the carefully designed steam trawler of to-day had not been dreamed of. Every innovation is an object of suspicion, especially among such conservative folk as fishermen are and Huxley was familiar with the complaints laid against the beam trawl before the royal commission of 1864 of which he was a member. The circumstances of to-day are very different and, whatever view may be taken of the controversial topic of over-fishing no one is now likely, with full knowledge of the evidence, to say that the operations of man are insignificant in their effects upon the composition of the stock of fish.

The Exhibition of 1883 gave impetus to a demand for scientific investigation of the sea and its resources which had already made itself felt. Ten years had passed since the "Challenger" sailed on her famous voyage. The Fishery board for Scotland had just begun systematic inquiries; abroad, notably in Germany, marine science was establishing itself and in Great Britain the next year was to witness the establishment of the Marine Biological Association of the United Kingdom. With the rapid development of fishing which followed the introduction of steam and, later (about 1895) of the otter trawl the old apprehensions were intensified and compelled the serious attention of the Governments, so that, when in 1899 the king of Sweden invited representatives of the countries interested in the fisheries of the North sea and the Baltic to a conference at Stockholm to discuss the subject of co-operation in the study of marine problems the response was general and, after a second conference in Christiania in 1901, the International Council for the Exploration of the Sea was constituted to co-ordinate the national researches of the participating countries. To-day all the countries of Northern Europe with important fishing interests are members of the Council, except Soviet Russia. Portugal, Spain and Italy are also members, having joined respectively in 1922, 1924 and 1927, and the Council's investigations cover the whole of the continental shelf of Europe and Northern Africa outside the Mediterranean.

In 1919 there was established the Commission Internationale pour l'Exploration de la Mer Méditerranée, fashioned in many respects on the model of the International Council, and in 1921 an analogous body was formed under the name of the North American Committee on Fishery Investigations to secure co-ordination of marine fishery investigations between the United States of America, Canada, Newfoundland and France.

The aim of economic marine biology is well summed up in the object set before it by the International Council for the Exploration of the Sea, which is "the rational exploitation of the sea." To exploit the sea rationally means, presumably, to get as much out of it as is possible at the least possible cost and without waste.

The first necessity is to know or at least to have a rational conception of what the stock of fish is and what are the factors governing these fluctuations of it which have puzzled and alarmed generations of fishermen. The first step in any such inquiry must take the form of statistics. The most complete and comprehensive statistics of sea fisheries are those of Great Britain. The International Council, which publishes an annual *Statistical Bulletin*, realises the importance of uniformity of method in the collection and presentation of statistics and is disposed to accept the British method as its model; but few of the constituent countries are, as

yet, as well equipped as Great Britain for their collection. The British statistics record annually the total landings of fish and of each of the most important food fishes separately. Such statistics are mainly of use for commercial purposes. The details required to supplement and guide biological investigations are many. The endeavour is made, in the case of each important food fish, to show from year to year the weight of fish taken, the range of size of the most important species the region in which they are taken, and the fishing power expended in their capture. Note is taken of the proportions of the different trade categories in the landings—"large," "medium" and "small"; but as these are variable dimensions, a check is kept upon these variations by measurers at the principal ports. Increased landings from any region may be the result merely of increased fishing: therefore note is taken of the number of voyages made and the length of time spent in fishing, from which is calculated the quantity of fish landed per day's absence from port, or, more lately, per 100 hours' fishing. Allowance has to be made, as well as may be, for increased size and power of the ships fishing, and for increasingly efficient gear. Having thus ascertained, as nearly as possible, the quantities of fish, in their different species, landed in a given period in different regions, the relation of this quantity to the power expended in its capture and the quality of the landings as regard the proportion of the totals falling into certain size categories, the calculations are further checked by special statistics collected on board a certain number of trawlers by fish measurers. The fish measurer takes mixed samples of the contents of the trawl after each haul and measures every fish in the sample. A considerable quantity of the fish taken are too small to be marketable, and are thrown overboard: but, since they are usually killed in the process of capture, they are lost to the stock. It is the business of the fish measurer to complete the picture furnished by the port statistics by revealing the quantity of undersized fish not landed, but, nevertheless, taken out of the total available stock. The actual stock on which we are working can never be accurately known: but the data collected by the methods just enumerated enable a reasoned opinion to be formed as to whether, making due allowance for all other factors, the stock is being overfished.

The chart on page 294 illustrates generally the method of comparison of landings with fishing power.

The chart presents two interesting features. The first is the similarity between the ascending curves of landings and of steam power employed until two new factors, the general adoption of the otter trawl and the development of fishing on the more distant grounds appear to be reflected in a steep rise of the curve of landings. The second is the high point at which the interrupted curve of catch per day's absence from port starts immediately after the war, during which little fishing had taken place, and its rapid decline apparently reflecting the influence of renewed fishing.

The following table of the landings of North Sea plaice is an interesting illustration of what appears to be the effect of fishing operations on the composition of the stock of a single species of fish.

The graph and the table are to be regarded merely as samples of the statistical data by means of which the endeavour is made to record changes of the stock (which, in the nature of things can, at best, only be estimated) and to form a reasoned opinion as to the relation between these fluctuations and the operations of men.

Such statistical data are the starting point of biological investigations and may furnish the test of provisional biological conclusions. In order that all factors affecting the stock of fish may be taken into account, it is necessary to study the life histories of the food fishes severally and collectively. Since the life histories of fishes, as of other animals, must be governed mainly by the factors of their environment, that environment must also be studied. The most important factors of the environment are, to express it very generally, climate and food, the former naturally reacting to a great degree upon the latter. What corresponds to climate in the sea is—again speaking in general terms—the physico-chemical composition and the movements of the water. It is an established fact that all animal organisms depend ultimately for their food supply in the sea, as on land, upon plant life.

Quantities (in 1,000 Tons) of Large, Medium and Small Plaice, Landed at English Ports from the North Sea by All Classes of British Vessels in Each Year from 1906 to 1927

	Large	Medium	Small	Total (excluding unsorted)
Pre-war 1906 . . .	10	7	9	26
1907 . . .	8	8	14	30
1908 . . .	8	8	13	29
1909 . . .	6	9	14	29
1910 . . .	5	8	11	24
1911 . . .	5	8	13	26
1912 . . .	5	9	11	25
1913 . . .	5	8	10	23
War 1914 . . .	4	6	10	20
1915 . . .	2	2	2	6
1916* . . .	1	2	1	4
1917* . . .	1	2	1	4
1918* . . .	2	9	2	13
Post-war 1919 . . .	9	13	2	24
1920 . . .	13	12	5	30
1921 . . .	6	11	6	23
1922 . . .	5	10	11	26
1923 . . .	3	6	12	21
1924 . . .	2	5	14	21
1925 . . .	2	4	16	22
1926 . . .	1	3	14	18
1927 . . .	1	4	16	21

*Estimated figures.

The fixed sea-weeds are found only in a narrow fringe in shallow water round the coasts, but in the upper water layers of the whole ocean to such depths as sunlight can penetrate are multitudes of microscopic plants, upon which above all depends the great productivity of the sea. These plants are eaten by various animals, which in their turn are eaten by larger ones, till at the other end of the food chain we find the fishes exploited by man, which thus ultimately depend upon vegetable growth. The plant harvest of the sea depends on many physical and chemical factors, the most important being suitable temperatures, an adequate supply of sunlight, of carbonic acid and of certain chemical salts.

FOUR BRANCHES OF RESEARCH

Thus, fishery research is divided broadly into four branches,—statistics, to which we have already referred, investigations of fishes; investigations of their food, including both the organisms, many of them microscopic, inhabiting the surface layers of the water and the invertebrates found at the bottom of the sea; and hydrographical investigations. In practically every instance conclusions have to be deduced from samples collected by ingeniously contrived, but as yet imperfect instruments. The factors to be taken into account are, moreover, so numerous and so complex and the area of inquiry so wide that the only hope of arriving at well-founded conclusions within a measurable space of time lies in organized team work. This fact has been recognized by the Governments of States represented in the International Council for the Exploration of the Sea in making themselves individually responsible for definite shares of a programme of work internationally organised through the Council. Neither must it be forgotten that the deep sea fisheries are for the most part prosecuted in waters in which all countries have equal rights of fishing. If, therefore, any practical results are to ensue from the knowledge acquired, in the form of regulation of fishing operations, or, as is not wholly inconceivable, actual cultivation of the stock, these measures must be applied with the goodwill and co-operation of all the interested countries.

A detail of the study of the life history of fishes of peculiar economic importance is the investigation of the rate of their growth and the variations of the rate of growth responding to different circumstances. For this purpose it is essential to have an index of age so that the growth rate of fishes of the same ages in different localities and circumstances and the variation of the growth rate generally at different stages of life or in favourable or unfavourable years may be compared. The ages of some fishes—notably of flat fishes—are fixed by counting the annual rings

in the ear bones or otoliths, of others—notably the herring—by counting similar rings in the scales. The technique of scale reading is by no means simple, and in the case of cod considerable difficulty has been experienced in accurate deductions of age from the scales.

Again, it is necessary to study the food of fishes by examination of the contents of the stomachs, and to correlate the information thus gained with information as to the distribution and abundance, from time to time of various organisms, pelagic or demersal, which furnish the food of different fishes or of the same fishes at different stages of life. That an adequate supply of suitable food is essential to healthy growth is axiomatic, and it has been suggested that the present rate of destruction of small fish might advisably be accelerated in order to promote the more rapid growth of the survivors. This raises the question of the amount of food which fishes can, at different stages of life, usefully consume. It may, however, be remarked that, if it were true, as appears to be established by evidence laid before the royal commission of 1864, that it was then by no means uncommon for a sailing smack, working on the most frequented (admittedly also the richest) grounds of the North sea to take from two to three tons weight of fish in a three hours haul with a beam trawl, whereas to-day the average daily take of a North Sea trawler using the otter trawl is something less than a ton, there seems, *prima facie* to be little cause to apprehend that the food supplies are, under present conditions, overtaxed.

It is also necessary to follow the migrations of the fishes, which can be most directly done, where such a course is practicable, by marking large numbers of them and offering rewards for well authenticated information as to the time and locality of their recovery. The technique of fish marking still requires elaboration, and is being carefully studied.

Some or all of these various methods of investigation have been applied and are being applied to the most important of the food fishes in accordance with programmes laid down by the International Council for the Exploration of the Sea. Those which have been most intensively investigated to date are the plaice and the herring, but investigation has also made considerable progress in regard to cod, haddock and hake, while other fish have received or are receiving attention as opportunity serves.

A classical example of the study of growth rate is that carried out in connection with the investigations of the plaice fisheries, where, by marking large numbers of young plaice, 7 to 8 in. long, taken in the shallow waters on the east side of the North sea, transplanting a proportion of them to the Dogger bank, where there is an abundance of suitable food, and leaving others where they were caught, it was proved that the transplanted fish developed at a remarkably greater rate than those left behind. The former, in 12 months grew about 5 in. in length and to nearly four times their original weight, while the latter grew little more than 2 in. in length and no more than doubled their weight.

An interesting illustration of deductions from scale reading is furnished by the investigations of Johan Hjort of the Norwegian herring fisheries, by means of which he showed that frequently and, indeed, usually, fish of a certain year group predominated over all other year groups over a series of years, whence it appeared reasonable to deduce that the stock of herrings from year to year depended mainly not upon regular annual accretions, but rather upon occasional floods from particularly prolific years. Hjort's examination of samples of Norwegian spring herrings in the seven years 1907–1913 revealed the presence of the following percentage of herrings of the 1904 year class:—1.6, 34.8, 43.7, 77.3, 70.0, 64.3, 64.7.

The most important examples of the study of the migrations of fish by marking are the experiments with marked fish conducted in connection with the plaice investigations, mentioned above and those with marked cod carried out by Hjort and reported in his *Fluctuations in the Great Fisheries of Northern Europe*; while a notable example of the study of migration by other means than marking is furnished by Schmidt's investigations of the eel, in the course of which, by following the larval eels, he traced the European eels to their spawning place in the Sargasso

sea.

The hydrographical investigations take the form not only of the study of the physico-chemical composition (and temperature) of the sea, upon which depends the harvest of the plant growth which, as already observed, is the beginning of the chain of marine life, but also of the movements of the water at the surface, near the bottom and in the intermediate layers, which govern to a great degree the actual distribution of the stock of fish particularly in the larval stages. For these purposes various ingenious instruments have been contrived and are constantly being improved upon; water bottles for the collection of samples at known depths, self-recording current meters, drift bottles adjusted to float at or near the surface, or to trail along the sea bottom. By means of such instruments and by many and various lines of investigation a few of which only it has been feasible to indicate above, the endeavour is being made to probe the mysteries of life in the sea.

PROVISION FOR RESEARCHES

The Government of Great Britain while taking direct responsibility, through the Fishery Board for Scotland and the Fisheries Department of the Ministry of Agriculture and Fisheries, for economic investigations, most of which are carried out in co-operation with the International Council, supports by liberal grants unofficial institutions devoted to marine research, on no other condition than that their work shall be of such a standard of excellence as to make it worthy of support. The chief of such institutions are the Marine Biological Association of the United Kingdom, with its headquarters and laboratory at Plymouth; the Dove Marine laboratory at Cullercoats, the oceanographical department of the University of Liverpool and the Scottish Marine Biological laboratory at Millport (*see MARINE BIOLOGY*).

The organization of fishery research varies from the country to country, but it can be stated in general terms that in practically every country of Europe provision is made for such researches in a greater or less degree, and with a greater or less measure of Government support; that in the United States of America the provision for fishery investigations partly under the direction of the States, partly under that of the central Government, is elaborate and costly; that in varying degree of development corresponding inquiries are in progress in most of the British dominions and colonies, and, indeed, in every country in which the economic importance of fisheries has gained recognition.

To pass under review the investigations of the last quarter of a century and their results up to date would be a gigantic task. No more has been possible here than to indicate briefly some of the lines of investigation and their aim.

The uses of science do not end with those studies which bear upon the capture of fish. The art and science of catching fish has developed far more rapidly than that of the disposal of fish when caught. The problem of keeping fish taken on distant voyages in a fresh state is not wholly solved by the use of ice. The fish which, in the course of a distant voyage go first into the hold, and, on return to port, come last out of it, are seldom fit for the fresh fish market; the present day methods of pickling herrings are practically the same as those invented by the Dutchman Beukels in the 17th century; the methods of production of fish oils are, as yet, imperfect. In almost every phase of the handling and use of fish there is work for the biochemist and in recent years the problem of how to make the best use of the fish when caught has been the subject of serious scientific study. Considerable progress has been made in devising methods of refrigeration suitable for application to fish, but there are many technical obstacles to be overcome. It is enough for the present to point out that the future development of the industry will depend not less, perhaps more, upon the improvements that science may devise in the methods of handling fish and fish wastes than upon the discovery of new resources or of improved and more intelligent practice in the capture of the living fish.

FISHERIES, LAW OF. As fishing is carried on both within and beyond regions over which national laws are in operation, any consideration of the law of fisheries naturally falls into two main divisions. Accordingly the national and the international aspects of the subject will be dealt with separately, the English law applicable within territorial waters (as to the extent of which see *WATERS, TERRITORIAL*) being explained in the first place.

English Law.—There is some confusion in the nomenclature used by early writers on the English law of fisheries, but the classification may be reduced to fisheries which are exclusive, and those which are not. In exclusive fisheries the right of fishing belongs to the owner of the soil, or is derived from him. These fisheries are sometimes referred to as "several" or "free." They may be corporeal, where they comprise both the soil and the fishing, or incorporeal, where they have been granted without the soil. Fisheries which are not exclusive comprise (1) common fishery, which is the right of the public to fish in tidal waters not appropriated as exclusive fisheries, and (2) common of fishery, where one or more persons have a right to fish in common with the person who owned the exclusive right. A fishery does not necessarily include all fish. Thus one person may own the soil and oyster fishery, and another the fishery for floating fish. Royal fish, *i.e.*, whales and sturgeons, are under the statute *De Praerogativa Regis* (1324) the property of the Crown and not of the finder.

"Ancient records from Domesday downwards show us that the most ancient and usual mode of enjoying the profit of fisheries, both in tidal and non-tidal waters, was by wiers, kiddels, fish-garths, stake nets, bucks, and other engines fixed into and permanently erected in the soil of the fishery" (Stuart Moore). Thus fisheries originally were profits of the soil over which the water flowed. This is still the general principle. The title to a fishery arises from the right to the soil. The rule is so well established that upon it has been based the converse proposition, namely, that ownership of a several fishery is evidence of the ownership of the soil (*Attorney-General v. Emerson*, 1891, A.C. 649). A fishery may be severed from the soil, or *solum*, and become a *profit à prendre in alieno solo* and an incorporeal hereditament, *i.e.*, a right exercisable over the property of another person. This broad principle is not restricted to inland or non-tidal waters. It gives to the owners of lands on the foreshore or within an estuary or elsewhere where the tide flows and reflows a title to fish in the water over such lands, and this is equally the case whether the owner be the Crown or a private individual. But in the case of tidal waters (whether on the foreshore or in estuaries or tidal rivers) the exclusive character of the title is qualified by another and paramount title which is *prima facie* in the public. "The common people of England" (wrote Lord Hale) "have regularly a liberty of fishing in the sea or creeks or arms thereof, as a public common of piscary, and may not without injury to their right be restrained of it, unless in such places, creeks or navigable rivers where either the king or some particular subject hath gained a propriety exclusive of that common liberty." The subjects of the Crown are entitled as of right not only to navigate but to fish in the high seas and tidal waters alike. This is probably a right enjoyed, so far as the high seas are concerned, by common prac-

tice from time immemorial, and it was probably in very early times extended by the subject without challenge to the foreshore (*i.e.*, to between high- and low-water mark) and to tidal waters which were continuous with the ocean, if indeed it did not in fact first take rise in them. The right into which this practice has crystallized resembles in some respects the right to navigate the seas or the right to use a navigable river as a highway. To the practice and the right there were and are exceptions. The king had the prerogative of excluding the right of public fishing in tidal waters. He could keep the fishery in hand, or grant it to a subject, but, since Magna Carta, no new exclusive fishery could be created by royal grant in tidal waters, and no public right of fishing in such waters, then existing, can be taken away without competent legislation. (This statement is summarized from the judgment of the privy council in *Attorney-General for British Columbia v. Attorney-General for Canada*, 1914, A.C. 153. Though the question at issue arose in relation to British Columbia, it was governed by the law of England, which, accordingly, was stated in the judgment.)

The public right above referred to depends upon the water being tidal and not comprised within the limits of any several fishery. There is no public right to fish in non-tidal waters, although navigable. The public right (which is subject to statutory regulations referred to later) includes the right of fishing over the foreshore (*i.e.*, between high- and low-water mark) when not within the limits of a several fishery, and of laying lines and drawing nets. It does not include the right of fixing stakes or fixed engines on the foreshore, or the right of drawing up boats above high-water mark and leaving them there for future use, though such rights may be gained by custom by fishermen in a particular locality. The public right does not include a right to appropriate part of the foreshore for the storage of oysters to the exclusion of the rest of the public (*Truro Corporation v. Rowe*, 1902, 2 K.B. 709). Oyster ponds or layings, it appears, may be the property of a private person, and may exist quite apart from the existence of a several oyster fishery (*Poster v. Warblington U.D.C.*, 1906, 1 K.B. 648).

The public rights of navigation must be exercised with due regard for the rights of owners of fisheries. If, by negligent navigation, injury is caused, *e.g.*, to an oyster bed, damages may be recovered. On the other hand, navigation must not be obstructed by, *e.g.*, the deposit of unreasonably large masses of oysters in the bed of a navigable river (*Mayor of Colchester v. Brooke*, 1845, 7 Q.B. 339).

Statutory Provisions.—The following are some of the principal statutory provisions as to British fisheries. By the White Herring Fisheries Act 1771 persons employed in these fisheries have the free use of all ports, harbours, shores and forelands in Great Britain, but subject to payment of dues for artificial harbours and piers. The Cran Measures Act 1908 legalizes the use of cran and quarter cran measures (regulated by the Herring Fishery [Scotland] Act 1815) in connection with trading in fresh herrings in England and Wales. The Herring Fishery (Branding) Act 1913 provides for the branding of barrels filled with cured herrings in England and Wales.

Under the Sea Fisheries Act 1868 the Ministry of Agriculture and Fisheries (formerly the Board of Trade) may make orders (operative when confirmed by act of parliament) for the establishment or improvement of oyster or mussel (and, by the Sea Fisheries Act 1884, cockle) fisheries on the shore and bed of the sea, or of an estuary or tidal river. A number of these orders have been made. The Fisheries (Oyster Crab and Lobster) Act 1877 prohibits the sale of oysters between certain dates, and the sale of edible crabs and of lobsters under a certain size.

The Sea Fisheries Regulation Act 1888, as amended by the Fisheries Act 1891, enacts that the Ministry of Agriculture and Fisheries may, by order, create sea fisheries districts, comprising any part of the sea within which British subjects have by international law the exclusive right of fishing, either with or without any part of the adjoining coast of England and Wales. An order must be laid before parliament, and may establish in each district a local fisheries committee, with power to make by-laws

regulating fishing. The by-laws become valid on being confirmed by the Ministry of Agriculture and Fisheries, and are enforced by fishery officers appointed by the committee. Under acts of 1891 and 1894 a local fisheries committee has powers to enforce statutory provisions with respect to shell-fish, which expression includes all kinds of molluscs and crustaceans.

The Fishery Board (Scotland) Act 1882 established a Fishery Board for Scotland, which was to take cognizance of everything relating to the coast and deep sea fisheries of Scotland and to administer the Herring Fishery Acts, a long series of statutes extending from the time of George III. onwards. By the Herring Fishery (Scotland) Act 1889 power was given to the Fishery Board to prohibit by by-law the methods of fishing known as beam and otter trawling in certain localities. By the Sea Fisheries Regulation (Scotland) Act 1895 the Fishery Board for Scotland, established by act of 1882, was reconstituted, and provision was made for the establishment of sea fisheries districts, including parts of the sea adjoining Scotland, and for the establishment of fishery district committees for the regulation of sea fisheries. The Trawling in Prohibited Areas Prevention Act 1909 prohibits the landing and selling in Great Britain of fish caught by beam and otter trawling in prohibited areas adjoining Scotland. (As to the Moray Firth see **WATERS, TERRITORIAL**.)

The Salmon and Freshwater Fisheries Act 1923 repeals nearly a score of former acts from 1861 onwards, and consolidates and amends their provisions. The act of 1923 prohibits certain modes of taking and destroying fish, and prohibits the taking of "unclean" or "immature" fish as defined by the act. Obstructions to the passage of fish, and times of fishing and selling and exporting fish are regulated. Provision is made for orders, to be made and confirmed by the Ministry of Agriculture and Fisheries, defining fishery districts, and establishing fishery boards to exercise certain powers given by the act, including the making of by-laws and the granting of licences to fish. Provisions are contained in the act as to inspectors, water bailiffs and other officers, and as to the recovery of penalties for offences. This consolidating statute extends only to England and Wales. The corresponding legislation applicable to Scotland must still be sought in a series of acts dating back for a century.

The Merchant Shipping Acts contain certain provisions applicable to fisheries. Part IV. of the principal act of 1894 as amended by later Merchant Shipping Acts deals with fishing boats. Its provisions, besides those applying to all fishing boats and to the whole fishing service, include others applying to (1) fishing boats of 25 tons tonnage and upwards and (2) trawlers. The provisions relate to the fishing boat register, discipline, casualties on board, disputes, apprenticeship, etc., and (with reference to trawlers) to the engagement, payment and discharge of seamen, and the certificates of skippers and second hands. The Regulations for the Prevention of Collisions at Sea (which are international in their application, but, so far as Great Britain is concerned, are operative under the provisions of the Merchant Shipping Acts) contain some provisions referring particularly to fishing vessels and fishing boats.

International Law.—Outside territorial waters fisheries are not subject to legal regulation, except where conventions have been entered into between States and have been made by legislation applicable to the subjects of the States which are parties to the conventions. Territorial waters may be regarded as survivals from mediaeval assumptions of sovereignty by maritime States over extensive areas of the high seas. Instances were the early Italian republics, the Scandinavian nations, Spain and Portugal. The English Queen Elizabeth contested the Danish, Spanish and Portuguese claims, but in the Stuart period a different policy, aimed at the Dutch, was pursued, and an extensive maritime jurisdiction was claimed by England. These extended claims to jurisdiction and to regulate fisheries have now mostly been expressly or tacitly abandoned or are maintained only in a modified form as (for instance) by Russia and Norway. (See **HIGH SEAS; WATERS, TERRITORIAL**.)

Instances of international fishery conventions are those entered into between Great Britain and the United States in 1818 and

1872 as to Atlantic fisheries (see the North American Fisheries Act 1819 and the Treaty of Washington Act 1872) and in 1892 as to the Behring sea fisheries (see Behring Sea Award Act 1894), those between Great Britain and France in 1839 and 1867 as to adjacent seas (see Sea Fisheries Acts 1843 and 1868) and in 1904 as to Newfoundland (see Anglo-French Convention Act 1904). The parties to the North Sea Fisheries Convention of 1882 were Great Britain, Germany, Belgium, Denmark, France and the Netherlands. This convention was confirmed by the Sea Fisheries Act 1883, and a further convention dated 1887 between the same parties respecting liquor traffic in the North sea was confirmed by the North Sea Fisheries Act 1893. A declaration respecting the North sea fisheries between Great Britain and Belgium was confirmed by the Fisheries Act 1891. As to seal fishery (1) on the eastern coast of Greenland see the Seal Fishery (Greenland) Act 1875, and (2) in the North Pacific see the Seal Fisheries (North Pacific) Acts 1895 and 1912, the latter having been passed to carry out a convention between Great Britain, the United States of America, Japan and Russia.

See S. A. Moore and H. S. Moore, *The History and Law of Fisheries* (1903); T. W. Fulton, *The Sovereignty of the Sea* (1911); H. J. W. Coulson and U. A. Forbes, *The Law relating to Waters* (4th ed., by H. Stuart Moore, 1924). (S. D. C.)

United States.—After the American Revolution the people of each State became themselves sovereign, and in that character held the absolute right to all navigable waters within their territorial limits, including the soil under them and the fisheries therein, for their own common use, subject only to the right of control and regulation of navigation which the Constitution of the United States reposes in the Federal Government. As in the absence of treaty stipulations Congress has no authority to pass laws to regulate or protect fisheries within the territorial jurisdiction of the States, this function rests with the individual States. In exercising the right of control and regulation of navigation, the secretary of war of the United States may grant permission for the use of fishing gear in areas in navigable waters under such conditions as he may prescribe where, in his opinion, it will not constitute a menace to navigation. The right of the States to regulate the fisheries extends to the three-mile limit of adjacent waters, with certain exceptions, e.g., in the Great Lakes, where such jurisdiction extends to the international boundary line. As laid down by the award of The Hague Tribunal (1910) the general principle with respect to bays is that the three marine miles are to be measured in a straight line drawn across the body of water at the place where it ceases to have the configuration and characteristics of a bay, and at all other places the three marine miles are to be measured following the sinuosities of the coast. In the case of large indentations the limits of exclusion are to be drawn three miles seaward from a straight line across the bay in the part nearest the entrance, at the first point where the width does not exceed ten miles. While the tendency of international law is to restrict jurisdiction over large coastal indentations, the rule is not absolute. Such large bays as the Chesapeake and Delaware are recognized as parts of the United States. As regards their local government the States are sovereign within their own limits and foreign to each other. An agreement between States, for example, affecting fisheries in boundary waters between them, to be binding, must be ratified by Congress. Such a treaty exists between the States of Washington and Oregon with respect to regulating the fisheries of the Columbia river. The Constitution provides that no State shall enter into any treaty, alliance or confederation. The exclusive right of regulating by treaty with foreign nations all matters which are the proper subject of international agreement has been taken away from the States and committed to the Federal Government. In treaties relating to the fisheries as in other matters this authority is supreme.

Under the provisions of the Constitution, Congress is empowered to make rules and regulations respecting the territory of the United States, and under this authority Congress makes the laws which are the basis for regulating the fisheries of Alaska and the District of Columbia. On the other hand the laws of the territory of Hawaii not inconsistent with the Constitution or the

laws of the United States or the provisions of the organic act continue in force, subject to repeal or amendment by the legislature of Hawaii or the Congress of the United States. Regulatory powers over the fisheries have been exercised by the territorial Government. Under the law of 1793, the right to engage in the coasting trade and the fisheries is restricted to U.S. vessels.

While it has been held that the high seas are the territory of no nation and no nation can extend its laws over them, means for exercising control over the operations of its own nationals and inhabitants on the high seas have been evolved. For example, a law of Congress, approved Aug. 15, 1914, makes it illegal to have on any vessel or boat of the United States engaged in sponging in the waters of the Gulf of Mexico or the Straits of Florida outside of State territorial limits sponges of less than a fixed diameter, or to possess any sponges of less than the said diameter sold or delivered by such vessels. By treaty two nations may control the operations of their nationals and inhabitants on the high seas. Thus under the terms of a convention between the United States and Great Britain for the preservation of the halibut fishery of the northern Pacific ocean, including Bering sea, ratified Oct. 21, 1924, the actions of the nationals and inhabitants and the fishing vessels and boats of the United States and of the Dominion of Canada are subject to certain regulations and restrictions including a closure to fishing for halibut for a fixed period of three months.

Under the convention between the United States, Great Britain, Japan and Russia, signed July 7, 1911, the citizens and subjects of the several nations named are prohibited from engaging in pelagic sealing in the waters of the north Pacific ocean, north of the 30th parallel of north latitude, including the seas of Bering, Kamchatka, Okhotsk and Japan. Importations of sealskins taken in restricted waters are prohibited, provision is made for a patrol and for the assignment of fixed percentages of the kill by the Governments having jurisdiction over the breeding grounds to certain of the other Governments. The story of the international complications that have arisen between the United States and Great Britain over the interpretations placed upon the intent and meaning of the several treaties regulating the fishing interests of the United States, Canada and Newfoundland, is a lengthy one. Suffice it to say that the first grant of fishing privileges was secured in 1783 with the conclusion of the treaty of peace between the United States and Great Britain and held until the opening of the war of 1812. Subsequently the convention of 1818 was entered into. Its provisions have been the basis of United States fishing rights in Canadian and Newfoundland waters much of the time since 1818, and with slight modifications, such as those under the award of The Hague Tribunal of Sept. 7, 1910, are still in force. It provides that American fishermen shall be admitted to enter the bays or harbours of Canada and Newfoundland "for the purpose of shelter and of repairing damages therein, of purchasing wood, and of obtaining water, and for no other purpose whatever." Under the provisions of the existing tariff law, the products of American fisheries are admitted duty free. (L. RA.)

FISHES, a name that has generally been applied to all those vertebrate animals that live in water, swimming by fins and breathing by gills. Most modern authorities agree in separating as a distinct class the lampreys and hagfishes, which have no gill-arches and no jaws. These are opposed as Cyclostomata (*q.v.*) or Agnatha to the remaining vertebrates, grouped together as Gnathostomata. The selachians (*q.v.*) are here also regarded as a class distinct from the true fishes, or Pisces, which are distinguished by having a more or less ossified internal skeleton, by dermal ossifications in the form of scales, bony plates and segmented fin-rays, and by the presence of an air-bladder, or lung.

The vertebral column differs from that of the selachians in having ribs that bound the abdominal cavity, which primitively meet in the tail region to form haemal spines, and in having a series of paired elements above the neural arches that meet above to bear an unpaired series of spines. This characteristic structure is well seen in the living Chondrostei and Dipneusti, but is modified by fusion and reduction in other fishes.

The dermal ossification on the body, where flexibility is a requirement, takes the form of juxtaposed rhombic bony plates

or "ganoid scales" in the more generalized forms; in most recent fishes the scales are rounded and overlapping by bony plates, including paired parietals and frontals on top of the skull, a parasphenoid below it, operculum, suboperculum and branchiostegals covering the gill-chamber and a series of four bones on each side overlying the pectoral arch and connecting it with the skull. Toothed bones, the premaxillaries and maxillaries, form the upper border of the mouth, and the primary upper jaw lies within the

BY COURTESY OF THE N.Y. ZOOLOGICAL SOCIETY

ANGEL FISH (*ANGELICHTHYS CILIARIS*) A CHAETODONT FROM THE WEST INDIES

mouth, is typically connected on each side with the ethmoid region of the skull, and is generally supported behind by the hyomandibular, which articulates with the skull. The septa between the gills are reduced, so that the gill laminae project as filaments; the gill-clefts lead into the gill-chamber, which has a single external opening. The air-bladder, originally a ventral diverticulum of the oesophagus, was perhaps first developed as an air-breathing organ. Several of the features that distinguish the Pisces from the Selachii, especially the premaxillaries and maxillaries, the bony skeleton, the air-bladder or lung, acquire additional importance because they are characteristic of all terrestrial vertebrates. The Batrachia or Amphibia differ from the Pisces especially in the structure of the limbs, in having true internal nostrils, and in the modification of the hyomandibular into the stapes, but the crossopterygian fishes of the order Rhipidistia are very close to the Stegocephalia, which are the most primitive four-footed vertebrates.

The class Pisces, even as here restricted, is the largest of all the vertebrate classes, including some 20,000 living species. Moreover, within it is found a greater diversity of structure than in any other class of vertebrates. It has been distinct from the Selachii from Silurian times, and there is no connecting link between them. These considerations, and the important structural characters outlined above, should leave no doubt that the Pisces are entitled to be regarded as a class from which the selachians are excluded. Fishes live under a great variety of conditions, at the surface of the sea, in mid-water, at the bottom, or buried in the sand or mud, some rarely approaching the coasts, some never far from them, and some never leaving the zones between tide-marks. In fresh-water they may frequent either slow rivers, mountain torrents, lakes, underground waters or swamps. Some are carnivorous, others herbivorous, others mud-eaters. They exhibit great diversity in form, coloration, size and shape of the fins, structure of the mouth and teeth, according to their mode of life.

Sub-classes and Orders.—For convenience of reference a list of the sub-classes and orders is given here, but a more detailed account of the classification follows the sections on anatomy, distribution, natural history, etc.

Sub-class 1. PALAEOPTERYGII. (*q.v.*)

- Order 1. Archistia
2. Belonorhynchii
3. Chondrostei
4. Cladistia

Sub-class 2. NEOPTERYGII. (*q.v.*)

- Order 1. Protospondyli
2. Ginglymodi
3. Halecostomi
4. Isospondyli
5. Haplomi
6. Iniomi
7. Giganturoidea
8. Lyomeri
9. Ostariophysi
10. Apodes
11. Heteromi
12. Synentognathi
13. Microcyprini
14. Salmopercae

15. Solenichthyes
16. Anacanthini
17. Allotriognathi
18. Berycomorphi
19. Zeomorphi
20. Percomorphi
21. Scleroparei
22. Hypostomides
23. Heterosomata
24. Discocephali
25. Plectognathi
26. Malacichthyes
27. Xenopterygii
28. Haplodoci
29. Pediculati
30. Opisthomi
31. Symbranchii

Sub-class 3. CROSSOPTERYGII. (*q.v.*)

- Order 1. Rhipidistia
2. Actinistia
3. Dipneusti

ANATOMY

Two general works on fishes contain good accounts of the anatomy, namely S. Bridge, *Cambridge Natural History, Fishes* (1904) and E. S. Goodrich, Lankester's in *Treatise on Zoology, Fishes* (1909) and to them the reader is referred for more details than are given below. A typical fish is spindle-shaped, laterally compressed, tapering towards the tail. The head is bounded behind by the gill-opening, in front of which are the gill-covers: the mouth is generally terminal, the eyes lateral; in front of the eye are the nostrils, two on each side. The body is covered with scales, and the lateral line series of scales, each bearing a tubule, extends backwards from above the gill-opening. The fins, each consisting of a membrane supported by fin-rays, include one or more dorsals on the back, a caudal at the end of the tail, and an anal on the lower side of the tail, generally beginning not far behind the anus, or posterior opening of the alimentary canal. The paired fins, which are homologous with the limbs of four-footed vertebrates, comprise an anterior pair, the pectorals, placed just behind the head, and a posterior pair, the pelvics.

Muscles.—The main longitudinal muscles of the fish which run backwards on each side are divided into an upper and lower portion by a horizontal septum and are divided into successive interlocking segments; the connective tissue, septa between which are attached internally to the vertebrae and ribs, appearing externally, if the scales be removed, as a double series of V shaped lines. The fins have their own series of muscles; the muscles of the eyes, jaws, etc. need not be described here.

Electric Organs.—The large electric organs of the electric eel are formed of modified muscular tissue, but those of the electric catfish are subcutaneous.

Alimentary Canal.—The alimentary canal in fishes shows a great diversity of structure, which has perhaps not been sufficiently studied for purposes of classification. The gut is generally differentiated into pharynx, oesophagus, stomach and intestine; a liver and a pancreas are present; in the Crossopterygii and Palaeopterygii and in a few primitive Neopterygii the intestine has a spiral valve, as in the Selachii.

Gills.—The gill-clefts, generally five in number on each side, are openings leading from the pharynx to the gill-chamber, which opens to the exterior. The septa between the clefts are reduced, so that the gill-lamellae, which in the selachians are attached to the septa for the whole or greater part of their length, project outwards and backwards as a double series of red filaments, supported by the skeletal arches in the walls of the pharynx. The gill-rakers, projections from the gill-arches in the opposite direction to the gill-filaments, may be absent or represented by a few knobs in piscivorous fishes, but in those that feed on minute organisms may be very numerous, long, slender and close-set, intercepting the food and keeping it from the gills.

Air-bladder.—The air-bladder in *Polypterus* and the Dipneusti agrees in its origin and its blood supply with the lungs of higher vertebrates, is sacculated in structure, and opens into the oesophagus by a mid-ventral glottis. In other fishes the air-bladder arises dorsally from the alimentary canal, and its duct, when present, opens into the upper part of the oesophagus, or sometimes into the stomach. The air-bladder may have been originally an air-breathing organ, and it retains this function in *Polypterus*, the Dipneusti and some primitive Neopterygii; in most fishes it has a hydrostatic function, secreting or absorbing gas so as to counteract the changes of pressure at different depths; in many it becomes connected with the internal ear, either by a chain of ossicles (Ostariophysi) or by means of anterior diverticula (Clupeidae, Mormyridae, etc.) and is an accessory organ of hearing; in others it is a sound-producing organ (some Siluroidea, Scaenidae, etc.).

The Kidneys are generally elongate, lying under the vertebral column for the greater part of the length of the abdominal cavity. The testes and ovaries are generally paired, elongate in form.

Vascular System.—The heart consists of a sinus venosus receiving the blood from the great veins, an auricle, and a thick-walled, muscular ventricle. In the Dipneusti the auricle and ventricle are incompletely divided into two. In front of the ventricle is

the ventral aorta, the enlarged and contractile, proximal end of which, known as the conus arteriosus, is long and has a longitudinal series of numerous valves in more primitive fishes, vestigial and with a single circle of valves in the higher Neopterygii. The blood is driven forward by the heart through the ventral aorta, which gives off paired arteries to the gills; dorsal vessels carry the oxygenated blood from these to the dorsal aorta, which sends forward carotid arteries to the head, and runs backwards below the backbone, sending off arteries to the muscles, viscera, etc.

Brain and Sense Organs.—In most living fishes the brain has a large cerebellum and no distinct cerebral hemispheres, but in the Dipneusti the cerebellum is small and the cerebral hemispheres are well-developed. The olfactory organs are a pair of pits with the lining epithelium produced into ridges, covered by the skin, and each with two nostrils, an anterior inhalent and a posterior exhalent. The eyes have a spherical lens, which can effect accommodation not by altering its convexity, but by changing its position with regard to the retina. In the internal ear a small projection of the sacculus—the lagena—represents the cochlea of higher vertebrates; solid calcareous concretions, the otoliths, are generally present in utriculus, sacculus and lagena. The lateral line system on the head and body consists of continuous canals containing sense-organs and communicating with the exterior of either by pores, or by tubes that perforate the scales. Whereas the internal ear is concerned with hearing and equilibrium, the lateral line is for the perception of movements of water.

Photophores.—The luminous organs found in many oceanic fishes e.g., stomiatoids, Iniomi, ceratioids, are glands with a luminous secretion. They may have a complex structure, with lens and reflector; they have been studied in detail by Brauer.

Teeth may be present in the jaws, on the inner surface of the mouth and pharynx, and in the Stromateidae even in the oesophagus. The teeth in the jaws are frequently conical, fixed, in several series; in piscivorous fishes they may be strong and acute, sometimes sharp-edged (e.g., Sphyraenidae), sometimes hinged and depressible inwards; in other fishes, according to the nature of the food, they may be incisor-like, blunt crushing teeth, slender and brush-like, small and cuspidate, or absent.

Scales.—The body of a fish is generally covered with scales, which in the most primitive types are juxtaposed, rhombic, bony plates or ganoid scales, arranged in parallel, oblique and longitudinal series, and in more advanced forms may be thin, rounded and overlapping. The work of Goodrich (1908) on the microscopic structure of the ganoid scales is of great value in classification. In the Palaeopterygii each scale consists of parallel layers of ganoine, a glassy substance, near the surface, and of bone within, separated by cosmine, a vascular layer with bunches of minute tubules arising from the channels nearest the ganoine. The scales of the Neopterygii differ in the absence of the cosmine layers, and in those of the Crossopterygii the cosmine has a very specialized and regular structure and is covered by only a single thin layer of ganoine. In most living Neopterygii the scales are thin, rounded and overlapping, with edges entire (cycloid scales), or denticulated (ctenoid scales). Some are entirely naked, others have a bony armour, which may be formed by the fusion of large secondarily ossified scales (e.g., *Ostracion*) or may be a new formation; in others the scales may be represented by spines.

Head-skeleton.—The cartilaginous cranium may be nearly or quite unossified, as in the sturgeons and lung-fishes, but this is probably secondary. Some Palaeoniscidae appear to have had lateral ethmoids, a large unpaired sphenoid in the orbital region, opisthotics on each side of the posterior part of the skull, and a basioccipital. These elements can be recognized in the skull of the living *Polypterus*. The early Crossopterygii appear to have had a somewhat similar structure, except that the sphenoid was postorbital in position. In the Neopterygii the cartilage bones are much more numerous; a basioccipital below and exoccipitals at the sides of the foramen magnum; five otic bones on each side, posteriorly an epiotic above and an opisthotic below, in front of the opisthotic a prootic, and above the prootic, a pterotic behind and a sphenotic in front; in the orbital region alisphenoids and orbitosphenoids, the latter often united to form a single bone;

In the ethmoid region lateral ethmoids. To these, found in *Amia* and *Lepidosteus*, is added in the Isospondyli an endochondral supraoccipital and a Y-shaped "basisphenoid," the vertical limb of which divides the entrance to the myodome or eye-muscle canal, which is bounded mainly by the parasphenoid and is roofed by inner shelves developed from the prootics. In several orders of Neopterygii some of these bones may be lost, the orbitosphenoid, basisphenoid and opisthotic being the least constant; in others modifications of the usual arrangement may be of value in classification, e.g., the enlargement of the opisthotic in the Anacanthini, and of the pterotic in the Solenichthyes and the meeting of the epiotics behind the supraoccipital in the Pediculati.

The dermal bones that cover the upper surface of the skull include paired parietals and frontals and at the sides of the parietals in most Palaeopterygii and Crossopterygii supra-temporals, which in the Neopterygii become cartilage-bones and are termed pterotics. Behind the parietals are the dermo-occipitals, generally one median and one on each side in the Crossopterygii, one or more pairs in other fishes. On the snout there are as a rule paired nasals, covering the olfactory sacs, and a mesethmoid, which in many Neopterygii ossifies downwards into the ethmoid cartilage. Below the skull is a large parasphenoid, which, except in the Crossopterygii, generally has ascending wings in front of the prootics; in front of the parasphenoid are the vomers, which in recent Neopterygii, except *Lepidosteus* and *Amia*, are united to form a single bone that often ossifies upwards in the ethmoid cartilage.

The upper border of the mouth is formed in the most primitive fishes by two pairs of bony plates with toothed edges, the premaxillaries in front and the maxillaries at the sides. In the Palaeopterygii the maxillaries are attached within to the ectopterygoids, but in the Neopterygii they are free, their front ends articulating with the ethmoid region of the skull. The premaxillaries are firmly fixed in most Palaeopterygii, and in the Cladistia, Protospondyli and Ginglymodi ossify through the ethmoid cartilage; in other Neopterygii they are generally loosely attached, and they may extend backwards, excluding the maxillaries from the oral border, and become protractile, developing a pair of posterior processes that slide on a median keel on the ethmoid.

The eye is surrounded by a series of circumorbitals, often incomplete above; behind, the cheek may be covered by the preoperculum (Archistia, Cladistia) or there may be other bones in front of the preoperculum, a large one in the Crossopterygii being regarded as the homologue of the squamosal of the Tetrapoda. In the Neopterygii the preoperculum is narrow, crescentic and firmly attached to the hyomandibular and quadrate.

The membrane covering the gill-chamber contains a series of bones attached to the hyoid arch, operculum, suboperculum and branchiostegal rays; in the Neopterygii there is an additional bone—the interoperculum—in front of the sub-operculum, below the lower limb of the preoperculum, and attached to the lower jaw. In front of the branchiostegals and between the rami of the lower jaw there are in some Palaeoniscidae a median and paired gular plates; the median gular persists in *Amia* and the Elopidae, and in the Crossopterygii and *Polypterus* the paired gulars are enlarged backwards, replacing the branchiostegal rays.

Visceral Arches.—The gill-arches, which surround the pharynx between the gill-clefts, consist of four pieces on each side, pharyngo-, epi-, cerato- and hypo-branchials; the last join a mid-ventral series of basi-branchials. There is a backwardly directed angle between the epi- and cerato-branchials, which are the principal gill-bearing pieces. Generally there are four complete gill-arches; behind the fourth the cerato-branchials of a fifth arch, termed lower pharyngeals, generally bear teeth that bite against teeth borne by the pharyngo-branchials of the preceding arches. The mandibular and hyoid arches are modified gill-arches, the palato-quadrate and lower jaw representing the epi- and cerato-branchials of one arch, the hyomandibular the epi-branchial of the next. The mandibular arch consists of the palato-quadrate and the lower jaw; the palato-quadrate has a palatine ossification in front, attached to the ethmoid region of the skull, and be-

hind two ossifications, a quadrate, to which the lower jaw is articulated, and a metapterygoid above; the membrane bones are a dermo-palatine, an ectopterygoid along the lower edge and connecting palatine with quadrate, and an entopterygoid above it. In the Chondrostei the palato-quadrate meets in front and are free from the skull.

The lower jaw has one or more articular bones and is sheathed by a number of bones, on the outside dentary in front, angular and supra-angular behind; on the inside a large prae-articular and in front of it, inside the dentary, a series of bones that may extend back above the prae-articular and by some authorities are termed coronoids. Such is the structure of the lower jaw in the Archistia, Protospondyli and Ginglymodi, but in the Rhipidistia there may in addition be a series of three or four bones below the dentary, the first of which is the homologue of the splenial of the Tetrapoda. In other fishes the number of bones is reduced by loss and by fusion; in some Neopterygii there are two only, dentary and articulo-angular.

The hyoid arch has no pharyngo- element, and the hyomandibular or epi-hyal, generally articulates with the otic region of the skull, and at its lower end is attached to the quadrate; but when the metapterygoid has an extensive articulation with the skull (Actinistia) the hyomandibular is small and free, and when the palato-quadrate fuses with the skull (Dipneusti) the hyomandibular is vestigial. In the Chondrostei the attachment to the quadrate is indirect, a separate cartilaginous element intervening. In the Neopterygii the lower part of the hyomandibular ossifies as the symplectic, a bone wedged in between preoperculum and quadrate, in the Protospondyli forming an additional articulation for the lower jaw. The hyomandibular supports the operculum and suboperculum and the principal lower elements of the hyoid arch, the cerato-hyals, bear the branchiostegal rays; a median basi-hyal, the front element of the basibranchial series, may form a "tongue" in the floor of the mouth cavity.

Backbone.—In the most primitive condition as in the sturgeons and lung-fishes, the vertebral column consists of the notochord, of paired cartilages above and below (neural and haemal elements) and of supraneural and infra-haemal arches. Of the neural cartilages, which protect the spinal cord, there are two to each muscle segment, a principal—basi-dorsal—and a smaller—inter-dorsal. The basi-dorsals bear a pair of rod-like pieces that meet above, forming supra-neural arches, and have articulated to their distal ends a median series of supra-neural spines. Below the notochord are basi-ventral and inter-ventral cartilages, the former in the trunk region bearing pleural ribs, which bound the abdominal cavity, running along the edges of the intermuscular septa; these are the ventral counterparts of the supra-neural arches. The presence of supra-neural arches and pleural ribs distinguishes the backbone of the Pisces from that of the Selachii.

In *Polypterus* and in most Neopterygii with a well ossified backbone the supra-neural arches are not distinct elements, but appear as slender processes, which may unite above; the supra-neural spines persist in most fishes, at least on the anterior vertebrae, but elsewhere are liable to suppression by the dorsal fin-skeleton. In some Protospondyli centra of a kind may be formed by the growth downwards round the notochord of the bony inter-dorsals, which may fuse with a similar upgrowth of the basi-ventrals behind them; in the tail these elements may remain separate, so that there are two centra to each muscle segment, an archless (inter-dorsal) and an arch-bearing (basi-ventral meeting basi-dorsal). In the Amiidae nearly solid centra are formed by the ossification of the tissue surrounding the notochord and the bases of the arches; in the tail, arch-bearing and archless centra alternate as in the Eugnathidae, Pachycormidae, etc., although their structure is quite different. In other Neopterygii the centra are formed in the same way as in *Amia*, but the tail vertebrae are undivided; in the more primitive Isospondyli the bases of the arches remain distinct from the centra, the basi-ventrals, or parapophyses, especially retaining their individuality as separate bones wedged into pits in the centra; in the more advanced types all the elements of the vertebra are co-ossified, and the parapophyses appear as processes bearing the ribs.

Fins.—Each fin consists of a membrane supported on each side by a series of ossified and segmented fin-rays. In the sturgeons the dorsal and anal fins are more primitive than in any other living fishes; each has a lobe at the base, containing a series of fin-muscles; there is an internal skeleton of a series of rod-like pterygiophores, each segmented into two principal pieces, basals in the body and radials in the muscular lobe of the fin; the fin-rays are much more numerous than the radials, which their inner ends overlap. Such a structure is characteristic of the Palaeopterygii. In the Neopterygii and *Polypterus* the lobe at the base of the fins is reduced and the radials are quite short; or are fused with the basals; the fin-rays are united in pairs and each is articulated to its own radial. Most Crossopterygii have two dorsal fins and one anal, differing in structure from those of the Palaeopterygii in the fusion of the anterior or all the basal segments of the pterygiophores to form a single bone. The caudal fin-rays articulate with the vertebral column.

BY COURTESY OF THE N.Y. ZOOLOGICAL SOCIETY

COMMON SUCKER (CATOSTOMUS COMMERSONII), ABUNDANT IN THE GREAT LAKES AND NORTHWARD. A FISH WITH PROTRUSIBLE MOUTH AND FLESHY LIPS ADAPTED FOR SUCKING UP MUD AND ORGANIC DEBRIS FROM THE BOTTOM

There can be little doubt that originally the tail was straight, but it is unlikely that any known fishes with a straight tail and the caudal fin equally developed above and below are primitive in that respect. In most primitive fishes the tail bends upwards and the lower lobe is more developed than the upper (heterocercal condition): in the lower Neopterygii and *Polypterus* the upturned part of the tail is so much shortened that the lower lobe becomes terminal and externally nearly symmetrical. In most Neopterygii the tail is homocercal, symmetrical, with not more than two or three upturned vertebrae, and with the upper hypurals, expanded haemal spines that bear the fin-rays, supported by the enlarged neural spines of posterior vertebrae, the centra of which have disappeared. In most Palaeopterygii the pelvic fins are similar to the anal. This is well shown in the living Chondrostei, especially *Psephurus*, in which the pelvic fin has a series of pterygiophores and differs from the anal in structure only in the more extensive fusion of the anterior basal segments to form a pelvis. The pectoral, from its position of greater importance, is more advanced in structure; the coraco-scapular cartilage, formed by the fusion of the anterior basalia, is firmly anchored by dorsal and ventral outgrowths; the posterior basalia unite to form a metapterygium. In the Neopterygii the pelvic fins are shortened, there are no basalia behind the pelvis, and the radials are reduced or absent, the fin-rays being inserted on the pelvic bones; the pectorals are as in the sturgeons in the more primitive orders, but in most there are no radials articulating with the metapterygium, which may persist as a bone that appears to be the lowest of a series of radials. The pectoral fins of the Crossopterygii differ from those of the sturgeons in that none of the radials articulates directly with the pectoral arch, and that the metapterygium projects outwards from the body, is segmented, and in the more advanced forms is long and bears radials on its posterior as well as its anterior side; the pelvic fins are similar, but are generally less specialized than the pectorals. These fishes have the fins more or less paddle-shaped, with long muscular lobes fringed with rays. The Actinistia are an exception, as in them the lobes are short and rounded, with a few divergent radials, perhaps articulating with the pectoral arch.

Pectoral Arch.—The primary pectoral arch, or coraco-scapular cartilage, may contain one or more ossifications. In most Neopterygii there are two, hypercoracoid above and hypocoracoid below, and in most Isospondyli and Ostariophysi a bony meso-coracoid arch.

The secondary pectoral arch consists of a series of four bones overlying the primary pectoral arch, strengthening it and connecting it with the skull; from above downwards post-temporal, supra-cleithrum, cleithrum and clavicle, the last meeting its fellow in a ventral symphysis; in the Belonorhynchii and Neop-

terygii clavicles are absent. In most Neopterygii the post-temporal has an upper fork attached to the epiotic and a lower to the opisthotic, but in some the lower fork is absent; in others the post-temporal is small, simple and united to the skull; in the Apodes, Opisthomi, etc., it is absent and the pectoral arch is unconnected with the skull.

COLORATION

The majority of fishes exhibit obliterative countershading, that is the colour grades from dark on the back to pale below, counteracting the effect of light falling from above and producing a uniform effect. In the sucker-fishes (*Echeneis*), which adhere to sharks, etc., and have their backs against and in the shadow of the object to which they cling, this type of coloration is said to be reversed, as it is in the black-bellied Batensoda, a catfish of the Nile that habitually floats upside down. Oceanic fishes that swim near the surface are generally blue above and white below, e.g., tunny, flying fish; from 100 to 500 metres below the surface occur large-eyed, silvery fishes with luminous organs, such as the Myctophidae, and at greater depths 500 to 2,000 metres, where there is little or no light, the majority of the fishes are uniformly blackish, have smaller eyes and often have luminous organs; the Macruridae, which are believed to live at the bottom in great depths, are uniformly coloured fishes with larger eyes than those that inhabit the middle depths, a curious feature as yet unexplained. Many coastal fishes are spotted, mottled or barred in such a way that they resemble the ground, or the rocks and weeds among which they live. Without observation of a fish in its natural surroundings it may be difficult to understand its coloration. A number of unrelated species of sea-perches are covered with hexagonal reddish spots separated by a pale network; a fish so coloured, when wounded, was observed by Alcock to take refuge in a clump of corals, where it lay concealed, the red spots exactly resembling the coral polyps.

Many tropical fishes have a brilliant coloration. The chaetodonts, characteristic coral-reef fishes, exhibit an extraordinary variety of markings, all of which, however, conform to Mottram's definition of concealing patterns, in that they break out at the margin and tend to conceal the shape.

Colour Changes.—The tropical sea-perches from Bermuda in the New York aquarium are of interest for their sudden changes of colour and markings, one species changing from yellow to red or brown, another turning on or off dark cross-bars and spots; under natural conditions the different colour-phases probably harmonize with different environments. The flat-fishes have long been known to simulate closely the ground on which they lie. Sumner, experimenting with a Mediterranean flat-fish (*Platophrys podas*) obtained some remarkable results by placing them on patterns such as black and white squares; on such backgrounds the fish responded more slowly than on sand, gravel or mud, but with practice changed more rapidly than at first. The capacity of this species to adapt itself is limited to the black, grey, brown and white of its usual habitat, and it has definite spots or markings that vary in relative intensity or may disappear, but always occupy the same position when present. Mast has found that flat-fishes of the genus *Paralichthys* can assume various colours that correspond closely to the background, although yellows and browns take much less time to copy than reds, greens or blues. These effects are produced by the concentration or distribution of granules of pigment in the pigment cells of the skin, under the control of stimuli received through the eyes. The flat-fish has to see the ground before it can resemble it, although there is no visual comparison of skin with ground. (See also p. 328d.)

LOCOMOTION

The locomotion of fishes has been studied by Breder (1926); in most fishes muscle segments of one side contract successively from head to tail, and then those of the other side, progression being accomplished by alternate strokes to right and left: this is the method adopted for rapid swimming by fishes of the normal spindle-shaped form. In swift oceanic fishes the dorsal and anal fins are generally small and serve as keels, the caudal fin is strong and forked, with pointed lobes, able to cleave the water; the

PAINTED FOR THE ENCYCLOPÆDIA BRITANNICA BY HELEN DAMROSCH TEE-VAN

BUTTERFLY FISHES AND THEIR ALLIES

1. *Heniochus varius*. Occurs in Samoa, where it is common among the reefs
2. *Holacanthus diacanthus*. Ranges from the Red Sea and Zanzibar to Polynesia
3. *Chaetodon triangulum*. Abundant from Sumatra to New Guinea
4. *Chaetodon ornatissimus*. Known from the Moluccas to Samoa, and to Hawaii
5. *Chaetodon fasciatus*. Ranges from the Red Sea to China and Hawaii
6. *Chelmon rostratus*. Occurs from east Africa to China

paired fins are pointed and are folded into the body in forward swimming, but are used in turning movements, in slowing down, etc. Such fishes have long narrow gill-openings, and the ejection of water through these—jet propulsion—is considered to be of considerable importance in forward movement.

The less active fishes may show great departures from the normal, in form, structure of the fins and methods of locomotion. Elongate fishes, such as eels or ribbon-fishes, move in a serpentine manner, curves alternately to one side or the other passing backwards along the body; undulating movements of the long dorsal or anal fins may assist. Deep-bodied fishes such as the plectognaths may keep the body nearly rigid, swimming by lateral strokes of the caudal and undulations of the dorsal and anal. Gobies, some wrasses, etc., swim by strokes of the pectorals.

BREEDING AND DEVELOPMENT

The majority of fishes come together in large shoals at the breeding season, when the eggs and sperm are extruded in the water. There is generally a migration to the breeding places, fresh-water fishes often making their way up-stream into the smaller rivers, or congregating on shallows, marine fishes seeking areas from which the eggs and larvae, if pelagic, will be carried by the currents in the right direction, or places where the ground is suitable for the eggs if these lie or are attached at the bottom. Some marine fishes, such as the shads, are anadromous, entering rivers to breed; other fishes that may feed and grow in fresh water breed in the sea; these are termed katadromous; the eels (*Anguilla*) and *Galaxias attenuatus* are examples. J. Schmidt has shown that many fishes are peculiarly sensitive to external conditions at the breeding season; for example the species of *Anguilla* require at this time water of a high temperature and a high salinity at about 500 metres below the surface; the migration of the European eel across the Atlantic is related to this need.

In most fishes there is no definite pairing and no care for the eggs and young. All the important northern food-fishes except the salmon, herring and shad produce great numbers of eggs that float in the sea; in some species of Gadidae a single fish sheds millions of eggs annually. The Salmonidae breed on gravelly shallows in rivers, and bury the eggs, so that these and the larvae are protected. Many Cyprinidae breed among weeds, to which the eggs adhere.

In other fishes there may be a definite courtship and pairing; it is among these that marked sexual differences may occur, the males being brightly coloured, with enlarged and beautifully marked fins; the eggs are generally few in number and are cared for by one or both parents, usually the male. A nest may be made, either by excavating and clearing a hollow at the bottom, as in some Centrarchidae and Cichlidae, by clearing a space among the weeds in a swamp (*Heterotis*, *Ophiocephalus*), or by cementing together bits of weeds (sticklebacks). In some Anabantidae the male blows bubbles that form a mass of foam floating on the water; as the eggs shed by the female fall through the water he collects them in his mouth and sticks them on to the under side of the nest, which he guards. In many Cichlidae the mother keeps the eggs in her mouth until they hatch; afterwards she swims with the brood, and opens her mouth for the little fish to swim into it at any sign of danger. Many gobies, cling-fishes, etc., lay their eggs in the shells of oysters or mussels, or on the under side of a stone. In the pipe-fishes and sea-horses the male receives the eggs into a groove or pouch on the under side of the tail or belly, and keeps them until they hatch.

Some fishes are viviparous, such as the Embiotocidae or surf fishes of the north Pacific, and many cyprinodonts.

Larvae.—The time of hatching and the size of the newly-hatched larvae vary greatly according to the size of the egg, some species starting life at a length of about 3 mm. The larva is generally transparent, with pectoral fins, a continuous median fin without rays, a notochord and a straight gut; the mouth may not be formed until the yolk-sac disappears, when the little fish begins to feed. As it grows the dorsal, anal and caudal fins appear in the continuous fin-fold, and the pelvics are developed. The tail is at first straight and symmetrical, and the first indication of a

caudal is the development of a mass of pro-cartilage, which later becomes the hypurals, below the notochord at some distance from the end of the tail; in connection with this the caudal fin-rays are developed; next the end of the tail turns upwards, so that the caudal fin becomes terminal, and the projecting end of the notochord, with its membranous fin, disappears. The ossification of the skeleton and other changes that give the young fish nearly the organization of the adult occur when it is quite small, usually less than an inch long. Some pelagic larval and post-larval fish have curious structures that disappear later, such as the long spines on the body of the larval *Mola*, or the long filamentous fin-rays of the larval *Trachypterus*.

The fins vary in their development, the dorsal appearing before the anal in the Clupeidae, the anal before the dorsal in the Iniomi. In some Nototheniiformes the larvae have large pelvic fins. In the Clupeidae the dorsal is fully developed far back, and then moves forward to its position in the middle of the length. In the young swordfishes both jaws are produced, and the lower becomes the shorter later on, but in the Belonidae the lower jaw is first prolonged and the upper grows out to equal it afterwards. In the Elopidae, Albulidae and Apodes the larval life is prolonged, the transparent compressed larva attains a considerable size, in some Apodes as much as a foot in length, and the change into the young fish is accompanied by a shrinkage in depth and length.

Among fresh-water fishes many larval adaptations may occur, such as adhesive organs (sturgeons, Lepidosirenidae, etc.) external gills (Lepidosirenidae, *Polypterus*), and the prolongation of the gill-filaments to the exterior (*Heterotis*, *Gymnarchus*).

DISTRIBUTION IN TIME

In Middle Devonian strata the Palaeopterygii are represented by Palaeoniscidae (*Cheirolepis*, *Rhadimichthys*) and the Crossopterygii by both Rhipidistia and Dipneusti, so that already the Pisces had had a long history and undergone considerable differentiation. The Palaeoniscidae flourished until the Jurassic, and with them from the Carboniferous the Platysomidae, and later, in Triassic times, another off-shoot, the Catopteridae. The Archistia became extinct in the Cretaceous period; the Belonrhynchii flourished in the Triassic and became extinct in the Jurassic. The Chondrostei began in the Jurassic with *Chondrosteus*, but little is known of other forms leading to the modern sturgeons, and of the Cladistia (*Polypterus*) no fossils are known. Throughout Palaeozoic times the Rhipidistia and Dipneusti flourished, but in the Triassic dwindled. The Ceratodontidae, represented to-day by *Neoceratodus* in Queensland, date from this period. The Actinistia ranged from the Upper Devonian to the Cretaceous. Thus the subclasses Palaeopterygii and Crossopterygii, which were dominant in Palaeozoic times, held on through the Mesozoic, during which most of the orders became extinct, and are represented to-day by a few remnants, the sturgeons, polypterids and lung-fishes.

The Neopterygii began in the Upper Permian with the Semionotidae, a family which flourished in Triassic and Jurassic times and gave rise to a number of other families of Protospondyli, which became extinct in or before the Cretaceous, except the Amiidae and Lepidosteidae, still living in North America. One Jurassic off-shoot of the Semionotidae, the herring-like Pholidophoridae, gave rise towards the end of the Jurassic to the Leptolepidae (Isospondyli), the first fishes with a true homocercal caudal fin, very near the Elopidae, which were abundant in the Cretaceous and are still in existence. During the Cretaceous the Isospondyli evolved and several off-shoots of this order appeared, notably the Iniomi (*Sardinioides*), the Heteromi (Halosauridae), the Apodes (Urenchelidae) and the Berycomorphi, these being the first spiny-rayed fishes. The earliest true perch (*Prolates*) appeared at the very end of the Cretaceous. The Tertiary history is very imperfect, but it is probable that most of the modern families date back to the early Eocene. In the Lower Eocene (London Clay) are a scorpaenid, and several sword-fishes and Scombridae. In the Upper Eocene of Monte Bolca occur several modern genera, and representatives of the Plectognathi, Pediculati, Discocephali, etc.

GEOGRAPHICAL DISTRIBUTION

Marine Fishes.—Fishes that live in the sea may be divided into oceanic and coastal fishes. The oceanic fishes include those that live at or near the surface, such as the tunny, bonito, flying-fish, many Myctophidae, etc.; those that swim generally from about 150 to 500 metres below the surface, mostly silvery, large-eyed fishes such as *Stylophorus*, *Chauliodus*, etc.; the bathypelagic fishes, usually blackish, occurring generally at depths greater than 500 metres below the surface; and finally the abyssal fishes, that live at or near the bottom of the ocean. The coastal fishes may live near the surface, as most Clupeidae, and Carangidae, may dwell on the bottom, either in shallow inshore waters, or on the continental shelf, the edge of which generally corresponds to a depth of about 200 metres, or on the slopes leading down to the abyss.

The microscopic plants, diatoms, etc., at the surface of the ocean are the basis of oceanic life; these are eaten by small pelagic Crustacea, etc., these again by the fishes, and the smaller fishes by larger ones. Some authorities have asserted that the small organisms that constitute the plankton are much more abundant in the colder seas than in the tropics, and consider that the importance of the northern fisheries is due to this. The truth is that plankton is more abundant in coastal waters than in the open ocean, and that although in northern waters there may in the right season be an abundance of plankton exceeding anything found in the tropics, this is no true index of annual production, growth and reproduction being quicker, and seasonal fluctuations less in the warmer seas. Moreover, the importance of plankton for bottom-living coastal fishes may have been overestimated. Petersen has found that detritus from the land and from seaweeds is the food of the bottom-living invertebrates on which these fishes feed. Descriptions given of the enormous shoals of gray-mullet, scombroids, etc., seen in tropical seas do not support the view that fishes are more abundant in colder waters. In the warmer seas there is a much larger number of species, and the number of individuals of any one species is consequently less; the herring must outnumber any of the numerous tropical species of Clupeidae. But the importance of the great fisheries of the north Atlantic, including the North sea, is not due to abundance of plankton, but to the presence of large areas less than 500 metres in depth, the grounds inhabited by the cod, plaice, etc.; it is these bottom-living fishes of the continental shelf on which the great trawling industries depend.

Little can be said of bathypelagic and abyssal fishes, except that some are known to have a world-wide distribution; others may be more restricted, but our knowledge is as yet incomplete. It is of considerable interest that the ridge, less than 1,000 metres in depth, extending from Scotland to Iceland and Greenland, is a barrier to *Macrurus*, which does not occur north of it. There is some evidence that species of *Macrurus* may be localized in parts of the Pacific from a similar cause.

Zones of Distribution.—For fishes that live not far from the surface, and for bottom fishes that live in inshore waters or on the continental shelf, temperature is a most important factor in distribution. For these fishes we may recognize a tropical zone, bounded by the mean annual surface isotherms of 20° C; north and south temperate zones, extending to the isotherms of 6° C and divided by that of 12° C into subtropical and subarctic or subantarctic zones; and arctic and antarctic zones beyond the 6° C isotherms. The tropical zone contains by far the greatest number and diversity of fishes. The oceanic scombroids, tunnies, bonitos, swordfishes, etc., the flying-fishes, the sun-fishes (*Mola*) are tropical and sub-tropical. The zone includes the coral-reefs and all the fishes that live in or near them, numerous Gobiidae and Blenniidae, pomacentrids, chaetodonts, plectognaths, Scariidae, the wrasses of the sub-families Julidinae, Novaculinae and Cheilinae, etc. The great majority of the perch-like fishes are tropical, including the Serranidae, Lutianidae, Pomadasidae, Sciaenidae, etc. The Clupeidae and Carangidae have many tropical genera. The flat-fishes are *Psettodes*, numerous Bothidae, Soleidae and Cynoglossidae.

There are two main divisions of the tropical zone, American and

Indo-Pacific. Jordan and Evermann, generally with good reason, separate generically most of the American species from their Old World allies. There are other American genera that have always been recognized as distinct, e.g., *Centropomus*, the nearest relative of which is the Indo-Pacific *Ambassis*. The fishes of the Pacific coast present a great similarity to those of the other side, most of the genera being the same, but the species different; this is due to the continuity of the two oceans in Eocene times across the isthmus of Panama. The Indo-Pacific region extends from East Africa to Polynesia; it includes many more genera and species than the American region. West Africa has a comparatively poor fauna, but shows more affinity to the Indo-Pacific than to America. Thus of the flat-fishes *Psettodes*, *Solea*, *Synaptura* and *Cynoglossus* are genera common to West Africa and the Indian ocean. It seems probable that in Eocene times, when the Mediterranean communicated with the Indian ocean, a tropical Indo-Pacific fauna extended through the Mediterranean to West Africa, and that the present West African fauna is mainly a remnant of this. The fishes found fossil in the Upper Eocene of Monte Bolca, Italy, include some genera now living only in the Indian ocean.

Southern Fishes.—South of the tropics the currents are not deflected by the land-masses to the extent that they are in the north; the isotherms are nearly parallel, and the seasonal fluctuations are relatively small, so that the zones of distribution are better defined. The sub-tropical areas include species of certain tropical genera and have other genera peculiar to them. An interesting feature is the presence of the same genus north and south of the tropics, for example *Box* (Sparidae) in the Mediterranean and at the Cape. *Sardina*, the pilchards or sardines, includes *Sardina pilchardus* of Europe, *S. sagax* with races from Japan, California, Chile and South Africa, and *S. neopilchardus* of South Australia and New Zealand. The hakes, *Merluccius*, have a somewhat similar distribution; they are mainly sub-tropical, but extend into the subarctic and subantarctic zones. Southern Australia and New Zealand are characterized by wrasses of the family Odacidae and flat-fishes of the sub-family Rhombosoleinae. In the southern subtropical zone Tristan da Cunha and St. Paul, some 4,000 miles apart, but on the same isotherm, have species in common, a *Labrichthys* and a *Chilodactylus*, found nowhere else in the world. A similar wide distribution of subantarctic fishes is found, southern New Zealand and the Magellan-Falklands area having three species of *Notothenia* in common.

Antarctic Fishes.—An important result of the recent Antarctic expeditions is to establish that the Falklands and South Georgia have entirely different fish-faunas, that of South Georgia being the same as that of Graham Land. The Nototheniiformes, with four families, constitute the bulk of the Antarctic fish-fauna, but the most primitive family, the Bovichthyidae, is more northerly, *Bovichthys* itself having species from Chile, Argentina, Tristan d'Acunha, St. Paul, Tasmania and New Zealand, and *Cottoperca* being confined to the Falklands-Magellan area. Of the Nototheniidae *Notothenia* has a number of subantarctic species distinct from the Antarctic ones; most of the other Nototheniidae, all the Bathyracnidae, and all the Chaenichthyidae except one species from the Falklands, are Antarctic. The Zoarcidae are represented in the Falklands-Magellan area by several peculiar genera, and in the Antarctic by two more.

Northern Fishes.—In northern seas the spreading of the currents produces the effect that the isotherms are close together in the west, but far apart to the east, so that the temperate zones are narrow in the west, but broaden out westwards; indeed, on the American side of the Atlantic the cold Labrador current comes into direct contact with the warm tropical water. The zones are less well-marked than in the south, but the same isotherms may be used; that of 12° C runs to the mouth of the English channel, which is near the northern limit of many Mediterranean species, near the southern limit of *Salmo* as a marine genus, and the region where the pilchard replaces the herring. Hjort enumerates cod, haddock, ling, tusk, plaice and halibut as important species found mainly in the North sea and northwards, and hake, pollack, sole, sea-bream, gurnards, etc., as occurring mainly south of the British Isles. P. Schmidt has shown that the Bering sea, the

Okhotsk sea and the north Japanese sea have each their own fishes. A most interesting example of discontinuous distribution is furnished by the Pacific herring (*Clupea pallasii*) which has an isolated colony in the White sea, with the Atlantic herring (*C. harengus*) along the coast outside.

The Arctic Zone.—The Arctic fish-fauna is a poor one; some Cottidae, with a few species of *Gadus* and *Pleuronectes*, appear to be confined to this region, and some of these may have a circumpolar distribution. Whether the isotherm of 6° C is the proper boundary for the arctic zone is open to question; it corresponds to the southern limit of certain arctic fishes, for example *Salvelinus* (char) as a marine genus; on the other hand several sub-arctic fishes, cod, halibut, herring, etc., occur round Iceland and along the northern coast of Europe about to the isotherm of 3° C.

Fresh-water Fishes.—Many marine fishes may enter fresh-water at times either to breed, or in search of food, and these may form fresh-water colonies that in time may become species. Thus there are fresh-water species of marine genera, and even fresh-water genera of marine families, such as the burbot (*Lota*), the only fresh-water member of the cod family. These are unimportant in distribution, but on the other hand there are families (e.g., Percidae) or even orders (Haplomi, Ostariophysi) that are true fresh-water fishes; and for them the sea constitutes an impassable barrier; their distribution is accomplished by hydrographical changes, such as the capture by one river of the tributaries of another, or the confluence of rivers brought about by an elevation of the land. Fishes of this kind are of great value in relation to problems such as the past history of continents indicating former unions or ancient lines of severances.

Australia and Madagascar.—Each of the great regions proposed by A. R. Wallace and P. L. Sclater for the mammals has a well-defined fish fauna, and the proposal made by some authorities to consider Madagascar distinct cannot be opposed from a consideration of the fishes, although its chief characteristics are negative. The Australian region and Madagascar, indeed, may be considered together, being characterized by the complete absence of Ostariophysi, except species of the secondarily marine Siluroid families Ariidae and Plotosidae. For the Australian region the only true fresh-water fishes are the archaic *Ceratodus* and a species of *Seleropages*, the other species of this genus inhabiting Borneo. *Seleropages* belongs to the Osteoglossidae, a primitive and widely distributed family, probably dating back to early Cretaceous times. The rivers of Australia and New Guinea contain many species of the marine families Ariidae, Plotosidae, Clupeidae, Serranidae, Atherinidae, Gobiidae, etc. Wallace's line may be regarded as the boundary between the Indian and Australian regions; the contrast between Borneo with its rich fauna of carps, loaches, cat-fishes, labyrinthic fishes, etc., and Celebes, without a single indigenous true fresh-water fish, is a striking one. Madagascar has none of the characteristic African families except a few peculiar Cichlidae, and as these are mainly brackish water species they do not negative other evidence that the severance of Madagascar from Africa is ancient, perhaps as ancient as that of Australia from Asia.

The Ostariophysi.—This order, comprising nearly 5,000 species, and including the characins, carps and cat-fishes, is dominant in the fresh-waters of all regions except Australia and Madagascar. The cyprinoids, the more generalized suborder, includes three divisions, Characiniformes, Gymnotiformes and Cypriniformes. The Characiniformes, with toothed jaws, are found in Africa and tropical America, attaining a much greater diversity in the latter; no genera are common to the two continents, but there appears to be a rather close relationship between the South American *Brycon* and the African *Alestes*. The Gymnotiformes, which may be regarded as highly specialized eel-shaped characins, are restricted to Central and South America. The Cypriniformes, distinguished by the toothless mouth and the falciform lower pharyngeals, include four families, the most generalized being the Cyprinidae. The headquarters of this family is in southern Asia, where there is a great variety of genera; the African species are numerous, but mostly belong to Indian genera, *Labeo*, *Barbus*, etc., and are probably the result

of a comparatively recent invasion. Many of the Cyprinidae of Europe and temperate Asia, and all in North America, are leuciscines, a group intermediate between the more primitive danionines and the cyprinines; the two last are more characteristic of India and Africa. The Catostomidae, or suckers, are restricted to North America, except for a genus with two species in China. The Cobitidae, or loaches, abound in mountain streams in central and southern Asia, and the Homalopteridae are loach-like fishes of India and South-east Asia.

Of the siluroids, or cat-fishes, South America has a large and varied assemblage, belonging to nine families, all endemic, including the primitive *Diplomystes* of Chile and such highly specialized forms as the Loricariidae, armoured, and with the lips forming a sucker. Africa and southern Asia have three families in common, one the Bagridae, rather closely related to the Pimelodidae of South America; each continent also has peculiar families. The Palaearctic region has few siluroids, *Silurus*, some Bagridae, etc. The North American cat-fishes are Amiuridae, a family closely related to the Bagridae.

Zoogeographical Regions.—From the distribution of the Ostariophysi the following regions may be recognized.

1. Australia, with the islands east of Wallace's line. No Ostariophysi except Ariidae and Plotosidae.
2. Madagascar. No Ostariophysi except *Ancharius* (Ariidae).
3. Neotropical Region. South and Central America. Characiniformes; Characinae in common with Africa, four endemic families. Gymnotiformes. Siluroidea; nine endemic families.
4. Ethiopian Region. Africa. Characiniformes; Characinae in common with South America, Citharinidae endemic. Cyprinidae; Indian genera. Siluroidea; three families in common with India, three endemic.
5. Indian Region: India and South-East Asia, with Java, Sumatra and Borneo. Cyprinidae numerous, mostly Danioninae and Cyprininae; Cobitidae; Homalopteridae. Siluroids numerous with endemic families.
6. Palaearctic Region. Europe, and Asia to the Himalayas and Yang-tse-Kiang. Cyprinidae; Cyprinines and many Leuciscines. Cobitidae. Siluroids few, of Indian families.
7. Nearctic Region. North America. Leuciscine Cyprinidae. Catostomidae. Amiuridae.

The distinctness of the different regions is emphasized when other fresh-water fishes are considered, for although the Palaearctic and Nearctic regions have in common the Haplomi (Esocidae, Umbridae) and the Percidae, North America is characterized by *Lepidosteus* and *Amia*, Hiodontidae, Amblyopidae, Percopsidae, Aphredoderidae, Centrarchidae, and the numerous dwarfed Percidae known as darters. Africa also has several endemic families, Polypteridae, Mormyridae, Kneriidae, Phractolaemidae, etc. As in Central and South America, there are in Africa numerous species of cichlid perches, but the fondness of some of these for brackish lagoons makes them, like the cyprinodonts, unreliable as evidence of former land connections. Much more important are the characins, and the Lepidosirenidae, with *Protopterus* in Africa and *Lepidosiren* in South America, the latter family specialized for fresh-water life in the tropics.

From the available palaeontological evidence it seems clear that the present distribution of fresh-water fishes was in the main accomplished at the beginning of the tertiary. In Eocene beds of North America occur Catostomidae, Amiuridae, Percidae and Centrarchidae. In Europe modern genera of Cyprinidae occur in Oligocene and Miocene deposits. It is generally accepted that in the Eocene the continents were isolated and developed peculiar faunas, and that at the end of the Eocene the present connections became established, joining North to South America, Africa and India to Eurasia, and in addition joining Asia to North America across the Bering sea. These connections allowed migrations and interchanges which produced considerable effects on the terrestrial faunas; but so far as can be judged they accomplished little for fresh-water fishes, beyond the introduction of leuciscines into North America from Asia, and of Cyprinidae and perhaps Clariidae from India to Africa. In Central America some neotropical types have penetrated to southern Mexico, but none has got on to the Mexican plateau. In the other direction the ancient *Lepidosteus* has reached Panama, and two or three nearctic genera are found in Guatemala. But it is a fair statement to say that the very distinct nearctic and neotropical fish faunas barely meet,

much less overlap, in striking contrast to the invasion of South America by northern mammals and reptiles.

To summarize, it appears that for fresh-water fishes, as compared with mammals, migration is much more difficult but survival more easy; the post-Eocene connections that enabled mammals to roam the world had little effect on the distribution of fresh-water fishes. These are, however, very important as a clue to the distribution of land and water in Cretaceous times, for it is almost impossible that the relationship between the fishes of Africa and South America is due to migration from the north. It seems probable that in early Cretaceous times South America and Africa were one continent, which extended to India, but not through Madagascar. In this continent the Ostariophysi originated and evolved, so that when it was broken up towards the end of the Cretaceous, these were at least Characidae and Pimelodidae in South America, Characidae and Bagridae in Africa, and Cyprinidae and Bagridae in India. Since then South Africa has been isolated and has developed its rich and remarkable fauna, colonizing Central America when the connection was established. India must have been connected with eastern Asia and thus with North America during some part of the Cretaceous, for the ancestors of the Catostomidae and Amiuridae reached North America from Asia before the Eocene.

MARGARET GRUNT (HAEMULON ALBUM), A MARINE PERCH OF THE FAMILY POMADARIDAE, PEARLY WHITE IN COLOUR. IT RANGES FROM FLORIDA TO BRAZIL

CLASSIFICATION

Sub-class 1. PALAEOPTERYGII.—Scales, when ganoid, formed of parallel layers of ganoine near the surface, and of bone within, separated by a layer of cosmine. Dorsal and anal fins with the dermal rays more numerous than their skeletal supports (except the dorsal of *Polypterus*), which typically form a regular series, with the radial segments well developed. Pectoral fin with one or more anterior radials articulating with the pectoral arch the rest with a metapterygium; pelvic with a well-developed series of radials, and often with the posterior basals free, not incorporated in the pelvis. Skull with few cartilage bones, lateral ethmoids, an unpaired sphenoid in the orbital region, a basioccipital and paired opisthotics being the usual ossifications. Maxillary firmly attached to ectopterygoid. Lower jaw without splenial or other bones below the dentary. No interoperculum and no symplectic. Clavicles present (except in the *Belonorhynchii*).

Order 1. **Archistia**.—Body usually covered with ganoid scales. Caudal fin heterocercal. Head covered with bones; preoperculum large, extending forward over cheek. Snout short; mouth normally formed, with fixed premaxillaries, and with palatines attached to ethmoid region of skull. Clavicles present. Vertebral column acentrous. This order includes the Palaeoniscidae, Platysomatidae and Catopteridae.

The Palaeoniscidae, which range from the lower Devonian to the end of the Jurassic, show a combination of primitive characters that entitles them to be regarded as the ancestors of all other fishes, except the Crossopterygii. They are elongate fusiform in shape, with a short and blunt snout projecting a little in front of the rather large mouth, which has acute conical teeth in the jaws. The dorsal fin is short, placed above or behind the pelvis. The Palaeoniscidae were evidently active, predacious fishes. Numerous genera are known, of which the Devonian *Cheirolepis* is remarkable for the long-based pelvic fins.

The Platysomidae, known from Carboniferous and Permian strata, are deep-bodied, with longer dorsal fin, smaller mouth and blunter teeth than the Palaeoniscidae. The Triassic Catopteridae differ from the Palaeoniscidae especially in the shortness of the upturned end of the tail.

Order 2. **Belonorhynchii**.—Body with four series of bony scutes. Caudal fin symmetrical. Snout and lower jaw very long; premaxillaries present, and palato-quadrates as in the Archistia. No clavicles. Vertebral column acentrous. The Triassic Saurich-

thyidae are pike-like fishes, whose structure has recently been elucidated by Stensio (1925).

Order 3. **Chondrostei**.—Body naked, or with vestigial scales, sometimes with series of bony scutes. Caudal fin heterocercal. Snout prominent: jaws toothless; premaxillaries absent; pterygo-quadrates meeting below skull, protractile. No preoperculum. Clavicles present. Vertebral column acentrous.

The Liassic Chondrosteidae differ from the modern Acipenseridae and Polyodontidae in having a series of branchiostegal rays. The Polyodontidae include *Polyodon folium*, the spoon-bill of the Mississippi, and *Psephurus gladius* of Chinese rivers. The Acipenseridae, or sturgeons (*q.v.*), differ in having the mouth smaller and more protractile, with a transverse row of barbels in front of it, and in having five series of bony scutes along the body. There are about 20 species of *Acipenser* from north temperate seas, entering rivers to spawn; several inhabit the Black and Caspian seas. *Scaphirhynchus* has four species, one from the Mississippi, three from the rivers of Tartary. All the Chondrostei are believed to feed mainly on small invertebrates found in mud, which they stir up with their snouts when feeding.

Order 4. **Cladistia**.—Scales, head skeleton, pectoral arch, etc. nearly as in the Palaeoniscidae; anal fin with rays more numerous than radials, and pelvics with well-developed radials; but other fins more specialized, the pectorals with one large radial articulating with the pectoral arch and numerous small ones articulating with a plate developed between them and the metapterygium; caudal abbreviate heterocercal (as in *Amia*); dorsal long, with each ray supported by its own basal, and all but the posterior ones spaced forming strong spines. No branchiostegals, but a pair of large gular plates. Vertebral column with bony centra. The single family Polypteridae inhabits the fresh-waters of Africa; it includes *Polypterus*, of which ten species are known, and the eel-shaped *Calamichthys*. As in the Dipneusti, the air-bladder is lung-like, and is used as an accessory organ of respiration. The larvae have a pair of large pinnate external gills.

Sub-class 2. NEOPTERYGII.—This sub-class includes the groups formerly known as Holostei and Teleostei; to it belong the great majority of living fishes. Its characters can best be understood by comparing the organization of its earliest and most primitive family, the Semionotidae, which ranged from the Upper Permian to the Jurassic, with that of the Palaeoniscidae, the only known fishes from which they can have been derived. The typical palaeoniscids appear to have been swift-swimming predacious fishes, with a large mouth and sharp teeth, whereas the Semionotidae were slow-swimming fishes, feeding at the bottom on shell-fish, etc., and had a small mouth with styli-form or tritorial teeth. Most of the differences between the Palaeoniscidae and the Semionotidae can be interpreted as related to this difference in habits. The dorsal and anal fins of the Palaeoniscidae, with numerous rays forming a close-set series, are fitted for cleaving the water and withstanding strains. In the Semionotidae the fin-rays are much reduced in number, are set well apart and are united in pairs; the muscular lobe at the base of the fin is reduced, the radial segments of the pterygiophores are shortened, and each fin-ray articulates with its own radial and has its own muscles. Such fins can perform the delicate movements needed by a fish at rest or swimming slowly. Correlated with this modification of the dorsal and anal fins is the shortening of the upturned end of the tail, so that the caudal fin becomes terminal, and the narrowing of the bases of the paired fins. The preoperculum, which in the Palaeoniscidae was a plate covering the cheek, became in the Semionotidae a strong crescentic bone firmly attached to the hyomandibular and quadrate, and the lower end of the elongated hyomandibular ossified as the symplectic, wedged in between quadrate and preoperculum, and at its anterior end forming an additional articulation for the broad lower jaw. This consolidation of elements is necessary for the articulation of a lower jaw that is massive and used for crushing. In the Semionotidae, as in the Palaeoniscidae, the operculum and suboperculum are the upper elements of a series of branchiostegal rays, but in the Semionotidae there is an additional bone of some interest, the interoperculum, which lies between the suboperculum and lower

jaw; it seems that the suboperculum, retaining its attachment to the posterior end of the lower jaw, has been elongated and fractured so that the posterior part may retain its freedom of movement, the anterior, overlapped by the lower limb of the preoperculum, being the interoperculum.

The Semionotidae also possess other important differences from the Palaeoniscidae that are not evidently related to different habits, e.g., the absence of a cosmine layer in the scales, the disappearance of the clavicles, more ossifications in the chondrocranium, etc. It is of interest that most of the adaptive features first acquired by the Semionotidae in relation to their habits have persisted in all the members of the sub-class, whatever their manner of life. Thus there are many swift and predacious Neopterygii, in which the dorsal and anal rays have increased in number and form a close-set series; but the skeletal supports have increased in number with them and thus the essential feature, that each ray articulates with its own radial is retained: such fishes have a widely forked caudal fin, but the upper fork is formed by the outgrowth of fin-rays, not by the upturned end of the tail; they may also have a large mouth, so that the preoperculum has no lower limb; but they retain the interoperculum, which was first developed in relation to a small mouth and a preoperculum with a long lower limb. The Neopterygii may be diagnosed as follows:—

Scales, when ganoid, of parallel layers of ganoine outside and of bone within, without a cosmine layer. Dorsal and anal rays equal in number to their skeletal supports, each articulating with its own radial, which is small, or fused with the basal. Caudal fin abbreviate heterocercal or homocercal. Pectoral fins with all or some of the radials articulating with the pectoral arch; pelvic fins with radials reduced or absent, the rays articulating with the pelvic bones. Typically a symplectic and an interoperculum. Skull typically with orbitosphenoids and alisphenoids and with five otic bones on each side. No clavicles.

Order 1. Protospondyli.—Caudal fin abbreviate heterocercal with all the hypurals supported by the upturned end of the vertebral column. Centra absent, or variously developed. Premaxillaries fixed, firmly attached to frontals, pierced for passage of olfactory nerves. Maxillaries movable, anteriorly articulating with ethmoid region of skull. Lower jaw with dentary, angular and supraangular on the outside, with large dentigerous prearticular on the inside, and with two articular bones for the quadrate and one for the symplectic, which articulates with it above and outside the quadrate. Hyomandibular firmly attached to quadrate, and preoperculum to both. One coracoid bone, or none; mesocoracoid bridge cartilaginous; one or more pectoral radials on metapterygium. Scales often ganoid.

This order includes a number of families found fossil in Mesozoic strata. The Semionotidae, with small mouth and short dorsal fin, the Macrosemiidae with a longer dorsal, the Eugnathidae, predacious fishes with large mouth, sharp teeth and forked caudal fin, the Pachycormidae, mackerel-like fishes, the Pycnodontidae, deep-bodied fishes with crushing teeth, resembling the modern Plectognathi, and the Aspidorhynchidae, in which the premaxillaries are prolonged into a beak, as in the swordfishes. The only living member of the group is the bowfin (*Amia calva*), a fresh-water fish of North America, belonging to a family that dates back to Cretaceous times and is distinguished from the Eugnathidae by the longer dorsal fin, rounded caudal, thin overlapping scales, and by the solid centra of the vertebral column.

Order 2. Ginglymodi.—Distinguished from the preceding by the structure of the jaws, suspensorium and opercles. Snout and lower jaw long; maxillary segmented, the first one or two segments attached to premaxillary, the rest to the ectopterygoid; metapterygoids articulating with transverse facets on wings of parasphenoid: hyoid arch free from pterygo-quadrate; preoperculum small, its anterior end articulating with a condyle on quadrate; interoperculum large, fixed, connecting hyomandibular with preoperculum. Vertebrae solid, opisthocelous.

Lepidosteus, with a few species from the fresh-waters of North America, is related to the Semionotidae, and differs from them especially in structural readjustments related to the prolongation of the jaws; the quadrate retains its anterior position, and the strain imposed on the suspensorium by the long and powerful

lower jaw is relieved by the support afforded by the metapterygoid articulation with the parasphenoid. The gar-pikes (*q.v.*) or alligator-gars, are sluggish piscivorous fishes with strong conical teeth; they are the only living Neopterygii with ganoid scales.

Order 3. Halecostomi.—Differ from the Protospondyli in that the premaxillaries are small and loosely attached, the maxillary has a convex oval border and bears two supplemental bones, and the lower jaw has no supraangular. Vertebral centra annular or biconcave. The Mesozoic Pholidophoridae had minute teeth, and were evidently plankton-feeders like the herrings, which they resemble in form and shape of the fins. The Oligopleuridae are distinguished by thin cycloid scales.

Order 4. Isospondyli.—Caudal fin homocercal, *i.e.*, the upturned end of the vertebral column is short, with not more than two or three centra, and the upper hypurals are supported by paired bones—uroneurals—that appear to be the enlarged neural arches of posterior vertebrae that have aborted. Fins without spinous rays: pelvics generally abdominal in position. Air-bladder with an open duct. Maxillaries generally forming part of upper border of mouth. Lower jaw without supraangular and without or with small praearticular. An endochondral supraoccipital. Coraco-scapular cartilage typically with three ossifications, including a mesocoracoid; pectoral radials articulating direct with pectoral arch, the lowest perhaps representing the metapterygium. Vertebrae biconcave. Scales not ganoid.

The principal families may be arranged as follows:—

- I. Parapophyses generally small distinct elements wedged into pits in the centra.
 - A. Oviducts generally complete.
 1. No photophores; mouth toothed, the maxillary, when well-developed, with two supplemental bones; branchiostegals five or more, no adipose fin. *Leptolepidae*, *Elopidae*, *Albulidae*, *Saurodontidae*, *Alepocephalidae*, *Clupeidae*, *Ctenothrissidae*.
 2. No photophores; mouth small, toothless; three or four branchiostegals; no adipose fin. *Chanidae*, *Kneriidae*, *Phractolaemidae*, *Cromeriidae*.
 3. Photophores present: *Gonostomatidae*, *Sternoptychiidae*, *Enchodontidae*, *Astronesthidae*, *Chauliodontidae*, *Stomiidae*.
 - B. Oviducts absent or incomplete; mouth toothed; not more than one supplemental maxillary; adipose fin usually present. *Salmonidae*, *Microstomidae*, *Argentinidae*, *Opisthoproctidae*, *Osmeridae*, *Salangidae*, *Retroppinnatidae*, *Haplochromidae*, *Galaxidae*.
- II. Parapophyses ankylosed with centra, appearing as strong processes.
 - A. Parietals meeting: entopterygoid articulating with a lateral peg on parasphenoid. *Osteoglossidae*, *Pantodontidae*.
 - B. Parietals meeting; air-bladder with an anterior vesicle on each side connected with otic region of skull. *Hyodontidae*, *Notopteridae*.
 - C. Parietals meeting; a large cavity on each side of skull, above the pterotic, containing a vesicle detached from the air-bladder. *Mormyridae*, *Gymnarchidae*.
 - D. Parietals small, separated by supraoccipital; mouth small, toothless. *Goniorhynchidae*.

The Jurassic and Cretaceous *Leptolepidae* scarcely differ from the *Elopidae*, also found in Cretaceous strata and represented to-day by two genera from tropical seas. They have a large terminal mouth with bands of small conical teeth, two supplemental maxillaries, numerous branchiostegal rays, a median gular plate behind the symphysis of the lower jaw, as in *Amia*, dorsal fin above or a little behind the many-rayed pelvics, and widely-forked caudal. *Megalops atlanticus*, the tarpon (*q.v.*) found on both sides of the Atlantic, is a much larger fish than its Indian congener. *Elops*, with seven species, is a widely distributed genus; these are silvery fishes, slender in form, and very active. The *Albulidae* differ from the *Elopidae* in having no gular plate and the mouth small, subterminal. *Albula vulpes* is a silvery fish found on sandy coasts throughout the tropics. *Pterothrissus gisu*, with long dorsal fin, is an albulid from deep water off Japan. The Cretaceous *Saurodontidae* are very near the *Elopidae*, but have stronger teeth. The *Alepocephalidae* are bathypelagic or abyssal, deep-blue, purple or blackish fishes, with the dorsal fin above the anal; some 50 species are known. The *Clupeidae*, with over 200 species, differ from the *Elopidae* in having no gular plate and in certain skeletal characters; paired anterior diverticula

of the air-bladder expand into vesicles inside the otic region of the skull. Most Clupeidae are marine, and swim in shoals near the surface, generally feeding on plankton. The herring, *Clupea harengus*, of the north Atlantic, is one of the most important food-fishes. *Sardina* includes the pilchards (*q.v.*) or sardines, found north and south of the tropics; *Sardinella* and *Harengula* are allied tropical genera. *Chirocentrus dorab* of the Indo-Pacific, a predacious fish with strong acute teeth, retains the spiral valve of the intestine. *Alosa* of the north Atlantic and Mediterranean comprises the shads, which enter rivers to breed; allied genera with similar habits are *Caspialosa* of the Black and Caspian seas, *Brevoortia* (menhaden) of the Atlantic coast of America and *Hilsa* of the Indian ocean. The anchovies (*Engraulis*, etc.) are small fishes of warm seas, distinguished by the projecting snout. *Chanos chanos* of the Indo-Pacific, the only species of the Chanidae, reaches a length of five feet; it feeds on algae and sometimes enters fresh-water. The Kneriidae, Phractolaemidae and Cromeriidae are small African fresh-water fishes. The Isospondyli with photophores, generally arranged in two rows along each side of the body, fall into two groups, the Gonostomatidae and Argyropellicidae, with two supplemental maxillaries and related to the Elopidae, and the more specialized Astronesthidae, Stomiidae, etc., with slender maxillary without supplemental bones. These are all oceanic, some living at considerable depths below the surface.

The Salmonidae are distinguished from related families with an adipose fin and without oviducts in that the last two or three vertebrae turn upwards at the base of the caudal fin. They are primarily marine fishes of arctic and northern seas that enter rivers to breed, but include a number of fresh-water species in Europe, northern Asia and North America. The principal genera are *Salmo*, salmon and trout (*q.v.*), *Salvelinus*, char (*q.v.*), *Coregonus*, whitefish (*q.v.*) and *Thymallus*, grayling (*q.v.*). The Argentinidae and Microstomidae are marine, deep-water or oceanic fishes, and the Osmeridae, or smelts, differ from the preceding families in having no orbitosphenoid, and in the presence of a series of teeth along the inner edge of the entopterygoid, characters that persist in the remaining salmonoid families, which, however, are distinguished by the loss of the mesocoracoid. The Osmeridae, like the Salmonidae, are northern marine fishes; they breed in inlets, estuaries or rivers, generally in brackish water. *Mallotus*, capelin; *Thaleichthys*, eulachon; and *Osmerus*, smelt (*q.v.*) are important genera, *Plecoglossus altivelis* is the ayu of Japan. The Salangidae of China and Japan are small, slender, translucent fishes. *Retropinna* of Australia and New Zealand differs from the Osmeridae mainly in the loss of the mesocoracoid and leads to the other southern families, the Haplochromidae, in which the premaxillaries extend nearly the whole length of the maxillaries, and the Galaxiidae, which have no adipose fin, the dorsal being above the anal. *Galaxias attenuatus*, from Patagonia, southern Australia and New Zealand, is remarkable in that it reverses the habits of its northern allies, descending to the sea to breed; the other species of *Galaxias* are mostly confined to fresh-water. The Osteoglossidae have large bony scales: they are unique among fresh-water fishes in their distribution. *Scleropages* has one species in Sumatra and Borneo, the other in Queensland and New Guinea. *Osteoglossum* has a single species from South America. *Arapaima gigas* of South America reaches 15 ft. in length. *Heterotis niloticus* is African. The little African *Pantodon* has large pectoral fins and is said to be a fresh water flying-fish. The Hiodontidae include only *Hiodon*, with three species from rivers and lakes of North America, large-eyed, silvery fishes. The Notopteridae, with a few species from lakes and marshes of Africa and southern Asia, differ in having the long anal fin confluent with the reduced caudal.

The Mormyridae (*see* MORMYR), with over 100 species from the fresh waters of Africa, are queer-looking fishes with restricted gill-openings, small eyes and generally a small mouth, which in some species is situated at the end of a long tubiform snout. A thin, loosely attached bony plate overlies the cavity in the side of the skull that lodges the vesicle which is in contact with the internal ear. *Gymnarchus niloticus* is allied to the Mormyridae,

but is eel-shaped. The Gonorhynchidae include only *Gonorhynchus* with few species from Japan, South Africa, Australia and New Zealand, slender fishes with spiny scales, a small toothless inferior mouth, and a prominent pointed snout with a barbel at the end.

Order 5. **Haplomi**.—Soft-rayed fishes with abdominal pelvic fins, with the maxillary entering the gape, and with an open duct to the air-bladder. Vertebral column with separate parapophyses inserted in pits in the centra, orbitosphenoid, and no mesocoracoid; mesethmoid represented by a pair of large dermal bones. Freshwater fishes of Europe, northern Asia and North America. Three families, each with a single genus. The Umbridae are small fishes. One species of *Umbra* inhabits central Europe, the other North America. The Esocidae are distinguished by the produced, flattish snout, the large mouth, the strong erect teeth of the lower jaw, and by having the premaxillaries widely separated from each other. The pikes are voracious, feeding mainly on other fishes. The Dalliidae differ from the Umbridae in having the pectoral radials represented by a cartilaginous plate. *Dallia pectoralis* is the blackfish of Alaska and eastern Siberia.

Order 6. **Iniomi**.—Soft-rayed fishes with pelvic fins abdominal or thoracic and pelvic bones free from the cleithra, air-bladder usually absent, when present with an open duct, mouth bordered above by the premaxillaries; pectoral arch attached to the skull by a forked post-temporal; no mesocoracoid; vertebral centra co-ossified with the arches; adipose fin generally present. A large and varied group of marine fishes.

Sub-order 1. *Myctophoidea*.—Pectoral fins lateral, pelvics below or behind them. Palatine normal, articulating with vomer. Cleithrum attached to lower end of supracleithrum. Four families.

The Aulopidae include the Cretaceous *Sardinoides* and the living *Aulopus* from the coasts of Australia and the Mediterranean, with a rather wide mouth with bands of conical teeth, a somewhat elongate dorsal fin followed by an adipose fin, and pelvic fins wide apart and placed below or a little behind the pectorals, inserted at the sides of the plate formed by the pelvic bones, which bears a pair of long posterior processes. The Synodontidae have a larger mouth with bands of depressible curved pointed teeth, the maxillary slender and adherent to or united with the premaxillary. *Synodus* and *Saurida* include a score of species from the coastal waters of warm seas. *Bathysaurus* has two species from deep water in the Pacific. *Harpodon* of the Indian ocean has the skeleton very feebly ossified and barbed teeth. The Sudidae differ from the Aulopidae in having a short dorsal fin, the pelvic fins close together, the pelvic bones simple triangular plates, no orbitosphenoid, etc. These are oceanic fishes, some living at considerable depths. *Chlorophthalmus* has a short snout. The other genera fall into two groups (*A*) with spatulate snout and with large mouth extending back beyond the eye, *Bathypterois*, *Ipnops*, etc. (*B*) More or less elongate and compressed, with produced snout, and mouth not reaching the eye, *Sudis*, *Paralepis*, etc. The Myctophidae are small silvery fishes with large eyes, and with rows of luminous organs on the body, inhabiting the ocean from the surface down to about 500 metres. The principal genera are *Neoscopelus*, *Myctophum* and *Lampanyctus*. The Rondeletidae and Cetomimidae, deep-bodied fishes with large mouth and dorsal fin above the anal, may belong here.

Sub-order 2. *Alepidosauroidae*.—Pectoral fins low, pelvics far behind them. Palatine large, firmly fixed to frontals and to ethmoid region of skull. Cleithrum attached near upper end of supracleithrum, which runs downwards and backwards and bears the post-cleithrum at its lower end. Fishes with a large mouth, with strong canines on the palatines and in the lower jaw, and with the premaxillaries and maxillaries slender and united posteriorly.

The Scopelarchidae are moderately elongate in form, with a short dorsal fin, and with slender barbed canines. The Omosudidae differ in having a produced pointed snout and compressed pointed canines. The Alepidosauridae are elongate, naked fishes with a long pointed snout, compressed teeth, and a very long dorsal fin; they are large oceanic fishes probably living at considerable depths. *Alepidosaurus* has four or five species from the Atlantic and Pacific. *Eugnathosaurus* is an Antarctic genus. The Creta-

ceous *Apateodus* may belong to this family, and the Dercetidae of the Cretaceous may be related.

Sub-order 3. *Ateleopoidea*.—Pectorals lateral, pelvics in advance of them, wide apart, each of a single ray, inserted at the sides of a cartilaginous pelvis which bears a pair of long posterior processes as in *Aulopus*. Skull in great part cartilaginous. Elongate, naked fishes, with short dorsal fin just behind the head, long anal joined to the small caudal, and small subterminal mouth. The genus *Ateleopus* includes about six species from the Indo-Pacific, living at the bottom in rather deep water.

Order 7. *Giganturoidea*.—Soft-rayed fishes without air-bladder, without pelvic fins and with long many-rayed pectorals high up, above and behind the small gill-openings. Mouth wide, bordered above by the long premaxillaries, which are united on the inside to the ectopterygoids; no maxillaries and no palatines. Gills small, widely separated from those of the other side, the lower parts of the gill-arches being undeveloped. Pectoral arch free from skull; no post-temporal and no supra-cleithrum; pectoral radials and coracoid ossifications thin plates. This order contains the single genus *Gigantura*, with four species from the Atlantic and Indian oceans. These are naked silvery fishes, with short snout, large telescopic eyes placed close together and directed forwards, slender acute depressible teeth in the jaws, and the lower lobe of the caudal fin elongate.

Order 8. *Lyomeri*.—Naked soft-rayed fishes with long slender tail, long dorsal and anal fins, no caudal, small pectorals and no pelvics. Gill-openings small. Mouth very large, bordered above by a pair of slender bones that meet in front and behind are attached within the quadrates, connected with head by loose skin; no palatine or pterygoid bones; hyomandibular-quadrates long, oblique; gills and pectoral arch far behind head, with reduced skeleton; skull with much cartilage and thin membrane bones; parietals meeting in front of supraoccipital. No ribs. No air-bladder. Oceanic fishes living at considerable depths, belonging to two families, each with a single genus and species. *Sacropharynx*, with curved pointed teeth and very distensible stomach, is piscivorous. *Eurypharynx*, with enormous mouth and minute teeth, may feed mainly on small invertebrates.

Order 9. *Ostariophysii*.—Closely related to the Isospondyli, but distinguished by a communication between the air-bladder and the internal ear through a chain of ossicles, which are modified elements of the four anterior vertebrae. An orbitosphenoid; generally a mesocoracoid.

This order contains some 5,000 species, nearly all fresh-water fishes. The most primitive members of the group are essentially similar in structure to generalized Isospondyli such as the Elopidae, but others, especially among the catfishes, depart widely in structure from that type. In spite of this diversity, all are held together by the essential similarity of the mechanism that transmits vibrations from the air-bladder to the internal ear and increases the sense of hearing. The air-bladder is divided into two parts, the anterior held by a strong pair of bones that represent the parapophyses, and ribs of the fourth vertebra; in its wall is embedded on each side a process of the *tripus*, a triradiate bone that represents the rib of the third vertebra, which is connected by a ligament with the *scaphium*, an ossicle which is the neural arch of the first vertebra, and is embedded in the wall of a membranous diverticulum of a cavity in the basioccipital bone that communicates with the perilymph spaces of the ear.

Sub-order *Cyprinoidea*.—The fishes of this sub-order are generally normally scaled. It comprises three well marked groups, the first including the characins, the second the electric eels, and the third the carps.

Characiformes.—In the characins the jaws are toothed, the maxillary enters the gape, and the upper and lower pharyngeals are toothed and opposed to each other in the usual way. The family Characinae includes several hundred species from Central and South America and about 50 from Africa. The African *Alestes* and the American *Brycon* appear to be closely related. *Hydrocyon* of Africa includes the tiger-fishes, distinguished by the strong pointed sharp-edged teeth. *Sarcodaces* is a pike-like fish from West Africa. Many of the South American forms are

small deep-bodied silvery fishes (*Tetragonopterus*, *Astyanax*, etc.) often seen in aquaria. *Serrasalmo* has a keeled and serrated abdomen, short but powerful jaws, and sharp-edged triangular teeth. Other South American families are the Gasteropelecidae, Xiphostomatidae, Anostomidae and Hemiodontidae. *Gasteropelecus* is remarkable for its deep, strongly compressed body with the thorax and abdomen expanded into a sharp-edged semicircular disc. Within this disc is a bony lamina formed by the union of the hypocoracoid bones, on which are inserted the very large muscles of the long pectoral fins. Eigenmann has seen these fishes skim along the surface of the water, with rapid beats of the pectoral fins, and finally emerge in a true flight. The Xiphostomatidae are carnivorous pike-like fishes. The Anostomidae have incisor-like teeth, or none, and probably feed on weeds, or some on mud. The Citharinidae include about 40 species from Africa; they have ciliated scales; the majority have a small mouth and small teeth, and are herbivorous.

The Gymnotiformes are South American fishes that differ externally from the characins in the anterior vent, long tapering

BY COURTESY OF THE N.Y. ZOOLOGICAL SOCIETY

SPOTTED MORAY (*MURAENA MORINGA*), AN EEL, ABUNDANT IN THE WEST INDIES. IT IS YELLOWISH IN COLOUR AND IS THICKLY MARKED WITH DARK SPOTS

tail with a very long anal fin and caudal small or absent, no dorsal or pelvic fins, and restricted gill-openings. The palatine and ectopterygoid are absent and the entopterygoid has an extensive attachment to the vomer and parasphenoid. The vertebrae are numerous, 70-250. There are four families. The Rhamphichthyidae and Sternarchidae are probably herbivorous; the different genera

parallel the Mormyridae in the diversity of the form of the snout, which in some is long and tube-like. The other families each contain a single species, *Gymnotus carapo* and *Electrophorus electricus*, the latter the electric eel (*q.v.*), which grows to a length of 8 ft. and discharges powerful electric shocks; the paired electric organs, formed of modified muscular tissue, occupy the lower half of the greater part of the fish.

The Cypriniformes differ from the characins in that there is no adipose fin, the mouth is toothless and protractile, and the lower pharyngeals are falciform, with teeth opposed to paired processes of the basioccipital that may unite below the aorta. In the Catostomidae the premaxillaries are small, the lips fleshy, the pharyngeal teeth in a single series, often numerous, and the pharyngeal processes of the basioccipital united to form an expanded perforated lamella, rolled up at the edges, and not covered by a horny sheath. These are the suckers, of which some 60 species are known from North America, belonging to *Carpiodes*, *Catostomus*, etc. *Myxocyprinus*, with two species from China, has a long dorsal fin like *Carpiodes*, as has *Amyzon* from the Eocene of North America. These fishes feed on small aquatic animals, weeds and mud; in the spring they swarm and run up the smaller streams to spawn. In the Cyprinidae, or carp family, the premaxillaries exclude the maxillaries from the gape, one or two pairs of barbels are often present; the pharyngeal teeth are in one, two or three series, are not numerous, and bite against a horny pad supported by the flat or concave lower surface of the basioccipital plate. This is a very large and widely distributed family, including at least 1,000 species. The form of the pharyngeal teeth, conical, molariform, compressed, etc., their number and arrangement, are of great importance in classification. The most primitive group is the Danioninae, mainly from southern and eastern Asia, but represented in Europe and Africa; the cleithra are rounded or pointed anteriorly. *Opsariichthys*, *Chela*, *Barilius*, *Danio*, *Xenocypris*, *Aspius*, *Pelecus*, etc., belong to this group. The leuciscines differ in that the cleithra are more expanded and truncated anteriorly; this group is well represented in Europe and northern Asia and all the American Cyprinidae seem to belong to it. *Leuciscus* (dace, chub, *q.v.*), *Rutilus* (roach, *q.v.*), *Xenocypris*, *Phoxinus* (minnow, *q.v.*), *Alburnus* (bleak, *q.v.*), *Abramis* (bream, *q.v.*), *Semiplotus*, *Rhodeus* (bitternling, *q.v.*), etc., are Old World genera. In the cyprinines of Eurasia and

Africa the cleithra are emarginate anteriorly; this group includes *Cyprinus* (carp, *q.v.*), *Barbus* (barbel, *q.v.*), *Labeo*, *Discognathus*, *Tinca* (tench, *q.v.*), *Oreinus*, *Gobio* (gudgeon, *q.v.*), etc. The majority of the Cyprinidae eat insects, worms, etc., or are herbivorous, but some have powerful jaws and are piscivorous. The Cobitidae, or loaches are small fishes with small scales; they differ from the Cyprinidae in having at least three pairs of barbels. The pharyngeal teeth are uniserial; the pharyngeal processes of the basioccipital do not unite and do not bear a horny pad; the anterior part of the air-bladder is in a bony capsule. Numerous species of this family inhabit mountain streams in tropical and temperate Asia; three are found in Europe and one in Abyssinia. The Homalopteridae are loach-like fishes with at least three pairs of barbels, with uniserial pharyngeal teeth, with pharyngeal processes of basioccipital reduced, and without horny pad. In skeletal characters they differ widely from the Cobitidae; the air-bladder is divided into two lateral sacs, each enclosed in a bony capsule. The mouth is sub-terminal or inferior, the lower surface of head and abdomen flat, the paired fins horizontal. There are ten genera from southern Asia. In *Gastromyzon* of Borneo the broad flat lower surface is margined by the long many-rayed pectoral and pelvic fins and by a lateral flap of skin between them, the whole forming an enormous suction disc.

Sub-order 2. *Siluroidea*.—The siluroids or catfishes (*q.v.*) have the body naked or covered with bony plates, with the mouth toothed and non-protractile, without parietals, opisthotic, symplectic or suboperculum, with first vertebra a disc rigidly united to basioccipital and to the second, third and fourth vertebrae which are ankylosed to form a complex, to which the fifth is rigidly attached, and with the parapophyses ankylosed to the centra. The mouth is generally furnished with barbels, a maxillary pair being the most constant, but one or two mandibular pairs being present in most families, and a nasal pair in some. The second ray of the dorsal and the outermost ray of each pectoral are typically strong spines, often serrated. The pectoral arch is highly characteristic; the post-temporal, when present, is a small plate rigidly attached to the skull; the supra-cleithrum is typically forked, the upper limb usually rigidly attached to the epiotic and pterotic, the lower to the basioccipital; the distal part, beyond the fork, forms a socket for the head of the cleithrum. A meso-coracoid is present except in the Ariidae, Doradidae and Bunocephalidae. The nuchal shield, found in many siluroids, is formed by a process of the supraoccipital and by expansions of the three first radials of the dorsal fin.

The air-bladder is divided by a partition into anterior and posterior divisions; the anterior is connected with the tripus, and usually extends laterally to beneath the skin above the pectoral fin. The complex vertebra bears a single transverse process, which is usually divided into an anterior branch, decurved and firmly attached distally to the stem of the supra-cleithrum, and a posterior horizontal branch; these branches support the anterior and dorsal walls of the anterior chamber of the air-bladder, which is also supported by the transverse process of the fifth vertebra. In the Doradidae, Pangasiidae, Mochochidae and Malopteruridae the anterior branch of the parapophysis of the complex vertebra loses its connection with the supra-cleithrum; its proximal part is a thin stem, its distal part an expanded plate inserted in the wall of the air-bladder and furnished with a muscle attached to the skull. This "elastic spring" mechanism is for the production of sound. In several families the posterior part of the air-bladder is absent, and the anterior is represented by two lateral portions, sometimes disconnected, and more or less encapsuled by the transverse processes of the fifth and complex vertebrae, which in the Trichomycteridae and Clariidae are complete bony cylinders, open only at their outer ends just beneath the skin, and with a fenestra for the insertion of the tripus. In some families (Callichthyidae, Loricariidae) the supra-cleithra and exoccipitals may share in the formation of the bony capsules, which open laterally by clefts or perforations in the supra-cleithral plates.

Most Siluroids have bands of pointed teeth and are omnivorous, but some with small mouth and incisor-like or bicuspid teeth are herbivorous, or feed on organic debris. The Diplomystidae in-

clude only *Diplomystes papillosus* of Chile and Argentina, the most primitive catfish, with a well-developed maxillary, expanded distally, and toothed. In all other siluroids the maxillary is small, slender and toothless. In most of them, as in *Diplomystes*, the dorsal fin has a spine and is anterior in position, an adipose fin is present, the anal is short or moderately long and the caudal is well-developed; in the following account the fins will be mentioned only when they have a different arrangement. In the Bagridae of Africa and southern and eastern Asia the anterior and posterior nostrils are wide apart, the latter usually with a barbel, the gill-openings are wide, and the air-bladder is large, not encapsuled. *Bagrus* and *Chrysichthys* in Africa, *Macrones*, *Liocassis* and *Rita* in Asia, are the principal genera. The Amiuridae of North America are closely related to the Bagridae. The Amblycepidae, small Asiatic cat-fishes, have the air-bladder divided into two lateral sacs, partly enclosed in bone. The Sisoridae are also Asiatic; they are found especially in mountain streams and have a flat lower surface and horizontal paired fins; the very strong parapophysis of the fifth vertebra extends outwards to the skin. In the more specialized forms the head is depressed, and the thorax may have longitudinal plaits (*Glyptosternum*) or the lips be expanded and reflected to form a sucker (*Exostoma*). The Amphiliidae of Africa also have a depressed head and expanded horizontal paired fins; the air-bladder is divided into two lateral parts enclosed in incomplete bony cylinders. The Chacidae include only the Indian *Chaca lophioides*, a fish with very large flat head and very wide terminal mouth; the caudal fin extends forward above and below, simulating a second dorsal and anal.

The Schilbeidae of Africa and India are very near the Bagridae, but have a long, many-rayed anal fin; in some specialized genera the dorsal fin is small and spineless, or is absent. The Indian *Entoplichthys* is remarkable for having a long, toothed bone, extending from the premaxillary to the corner of the mouth, simulating a maxillary; but the true maxillary, reduced, toothless and bearing barbels, is also present. The Indian *Pangasius* also has a long anal fin, but the air-bladder has an elastic spring mechanism. The Mochochidae of Africa have an elastic spring apparatus; they have the external characters of the Bagridae, except that there is no nasal barbel and the gill-openings are restricted; the nuchal shield is strongly developed. *Synodontis*, with branched barbels, is the largest genus. The Malopteruridae include only the African *Malopterurus electricus*, without dorsal fin and with a subcutaneous electric organ extending over the whole body; the air-bladder has an elastic spring mechanism. In the Siluridae of Europe and Asia the body is elongate, the dorsal, when present, is small and spineless, the adipose fin is absent, and the very long anal is contiguous to and continuous with the caudal. *Silurus glanis* is the "Wels" of Europe. The Clariidae of Africa and India are elongate, with depressed head, transverse terminal mouth, four pairs of barbels, spineless dorsal and long, many-rayed anal; the cranial roof-bones are expanded, forming a shield. Above the gills is an air-breathing sac. The air-bladder is divided into two lateral portions enclosed in transverse bony cylinders.

The Ariidae, found on coasts and in estuaries throughout the tropics, are primitive in form, in the structure and position of the fins, but in skeletal characters they are more specialized than the Bagridae. The Plotosidae of the Indo-Pacific are elongate, without adipose fin and with a very long anal confluent with the caudal. In some species the caudal fin extends forward along the back, simulating a second dorsal fin, but having no skeletal supports for the rays. *Plotosus* is a widely distributed marine genus; *Copidoglanis*, *Cnidoglanis*, etc., are restricted to the rivers of northern Australia and New Guinea.

Of the Siluroids of South America the Pimelodidae scarcely differ from the Bagridae, but have no nasal barbel. There are numerous species of *Rhamdia*, *Pimelodella*, etc. *Platystoma* has a long spatulate snout. The Doradidae resemble the African Mochochidae in their restricted gill-openings and large nuchal shield; but in skeletal structure they are quite different, and even the elastic spring apparatus is formed on another plan. *Helogenes* is the type of a distinct family; the spineless dorsal is placed

above the long anal. *Hypophthalmus*, also forming a separate family, has a toothless mouth, eyes behind and below the angle of the mouth, a very long anal, united lower pharyngeals, and air-bladder reduced to two small sacs, each enclosed in a bony capsule with a lateral opening beneath the skin. The Trichomycteridae have a spineless dorsal and no adipose fin; the air-bladder is divided into two lateral sacs in bony capsules, which, except in *Cetopsis*, are united to the skull. In most of the genera the operculum and interoperculum are armed with spines. *Stegophilus* and *Vandellia* are small, slender fishes parasitic in the gill-cavities of other fishes. The Bunocephalidae have a broad flat head, the gill-openings reduced to small holes, and no adipose fin. In the Callichthyidae and Loricariidae the air-bladder is reduced to a pair of sacs enclosed in bony capsules that are united with the skull. In the Callichthyidae the body is covered on each side with two series of thin overlapping bony plates. In the Loricariidae the body is generally covered with bony scutes, anteriorly in five longitudinal series on each side; the small mouth is inferior, with expanded lips forming a sucker; the upper part of the gill-opening is inhalent. These are herbivorous or mud-eating fishes, with a very long intestine coiled like the spring of a watch; their oral sucker enables them to fasten on to rocks. *Cyclopium*, with about 15 species from mountain streams of the Andes, is naked, the absence of carnivorous fishes rendering the bony armour unnecessary.

Order 10. **Apodes**.—Soft-rayed fishes with an open duct to the air-bladder and with the pelvic fins, when present, abdominal. Body elongate; gill-openings small; dorsal and anal contiguous to or continuous with the caudal; pelvic fins usually absent. Skull long; premaxillaries, mesethmoid and lateral ethmoids represented by a single toothed bone, which separates the maxillaries; parietals meeting; pterotic extending forward to alisphenoid above sphenotic; no opisthotic; paired orbitosphenoids. No symplectic; a single palato-ptyergoid bone, or none. Opercular bones small, the long branchiostegals supporting the skin covering the large gill-chambers. No post-temporal; supra-cleithrum attached to vertebral column by ligament; no mesocoracoid. Vertebrae numerous; arches ankylosed to centra. No oviducts. A *Leptocephalus* larva. The peculiarities of the skull, jaws, suspensorium and pectoral arch separate the Apodes, or eels (*q.v.*), very sharply from the Isospondyli. They are carnivorous and marine, except that the species of *Anguilla* enter fresh water. All the Apodes have a remarkable developmental history, the larvae being strongly compressed and transparent, with a single series of slender, pointed teeth in the jaws. These larvae are known as *Leptocephalus*; they live near the surface of the ocean and feed on minute organisms; when they have attained a certain length, which in some species may be as much as a foot, they cease feeding, shrink in depth and in length, become compact and opaque, lose their larval teeth and undergo other changes that convert them into small eels.

The Cretaceous Urenchelidae are primitive eels with the caudal fin free from the dorsal and in one genus, *Anguillavus*, with small, eight-rayed pelvic fins. In all other Apodes the caudal fin, when present, is continuous with the dorsal and anal, and pelvic fins are absent. There are 17 families, that may be divided into two groups, one with paired frontals, the other with the frontals united to form a single bone. Of the families with paired frontals the Anguillidae contain the single genus *Anguilla*, with species from the north Atlantic, Japan and the tropical Indo-Pacific. Related to the Anguillidae are the Simenchelidae, which include *Simenchelys parasiticus*, an eel with transverse mouth and incisor-like teeth from deep water in the north Atlantic, that is often found burrowing in the flesh of the halibut. The Myrocongridae, with a single species known from St. Helena, resemble the Anguillidae in having pectoral fins, but approach the Muraenidae in having the pharyngeal openings of the gill-clefts narrow and the palato-ptyergoid very slender. The Muraenidae, or morays (see MURAENA), include more than 100 species, voracious eels from tropical and sub-tropical seas, abounding in the crevices of coral reefs; many have strongly marked colour patterns. They are naked, with small round gill-openings and without pectoral

fins, distinguished by having "pharyngeal jaws," the upper and lower pharyngeals being long bones, each bearing a double series of strong teeth, supported by the much enlarged epi- and ceratobranchials of the fourth gill-arch.

The Heterenchelidae of West Africa and the Moringuidae of the Indo-Pacific have the vertical fins well developed only near the end of the tail; they have small eyes, and a prominent otic bulla formed by the prootic and exoccipital. The Nemichthyidae are oceanic eels, very elongate, with the snout and lower jaw very long and slender, and with numerous small teeth regularly arranged in quincunx. The Cyemidae include a single species, *Cyema atrum*, an oceanic fish with the jaws and teeth of a *Nemichthys*, but with short body, and with the dorsal and anal fins highest posteriorly and separated by a notch at the end of the tail, simulating a forked caudal.

The families with the frontals united to form a single bone fall into two groups, the congers and their allies having strong jaws and a well-developed palato-ptyergoid, the Synphobranchidae, etc., having slender jaws and the palato-ptyergoid very slender, or absent. The Muraenesocidae comprise the single genus *Muraenesox*, found in tropical seas, large voracious eels with strong canine teeth. In the Congridae the maxillaries articulate near the end of the snout, the caudal vertebrae have transverse processes, and the nostrils are lateral. This is a large and varied family; some of the species live in shallow water, others at considerable depths. The Echelidae, differing in having the nostrils in the upper lips, are small worm-like eels inhabiting sandy coasts in tropical seas. The Ophichthyidae also have labial nostrils, but have no caudal fin, the tip of the tail projecting beyond the dorsal and anal. There are more than 100 species from tropical seas, especially abundant about coral reefs; many are banded or spotted with bright colours. The Synphobranchidae are deep-sea eels with the gill-openings confluent into a single ventral slit.

Order 11. **Heteromi**.—Air-bladder without duct, but vertebral column primitive, with the parapophyses separate elements. Skull elongate, with parietals meeting above supraoccipital and parasphenoid joining sphenotic; basisphenoid, alisphenoid, orbitosphenoid and opisthotic absent; post-temporal simple or ligamentous. A long tail, with a long anal fin below it, tapering to a point, without caudal fin; pelvic fins abdominal, many-rayed. No oviducts. These are oceanic fishes, living at considerable depths; about 25 species are known. In the Halosauridae, the mouth is bordered above by the premaxillaries and maxillaries, both toothed, the dorsal fin is short and there are no spinous fin-rays. In the Lipogenyidae (*Lipogenys gillii* from the north Atlantic) the mouth is small, toothless and thick-lipped, and the anterior rays of the dorsal and anal and the outer rays of the pelvic fins are spinous. In the Notacanthidae the mouth is bordered above by the toothed premaxillaries; the pelvic and anal fins are as in the Lipogenyidae, but the dorsal is represented by a series of isolated spines.

Order 12. **Synentognathi**.—Soft-rayed physoclists with abdominal, six-rayed, pelvic fins, and with the lower pharyngeals united to form a single bone. Premaxillaries non-protractile and maxillaries entering gape to a greater or less extent; lower jaw with laminar prearticular. Parietals, if present, very small, separated by supra-occipital; no orbitosphenoid and no opisthotic; epiotic and pterotic produced back into a lamina, to which the post-temporal is attached; supra-cleithrum reduced; pectoral radials short, rigidly attached. Fishes with cycloid scales, low lateral line, dorsal fin above the anal, and pectoral fins placed high. The large number of branchiostegals (9–15), the structure of the mouth, the absence of spinous rays, the truly abdominal pelvic fins, etc., indicate their derivation from the Isospondyli.

Sub-order 1. *Scombresocoidae*.—Scales small; jaws produced. Third upper pharyngeals moderately enlarged, separate; lower pharyngeal triangular or long and narrow. Cleithrum connected with basioccipital by a strong ligament. The Belonidae, or gar-fishes, are coastal fishes of warm seas, generally swimming near the surface and feeding on small fishes. The principal genera are *Belone* and *Tylosurus*, the latter with stouter jaws and stronger teeth. *Potamorhaphis* comprises some small fresh-water species

from the Malay archipelago. The Scombroideae include *Scombrox saurus*, a widely distributed oceanic species, with minute teeth and with a series of detached finlets behind the dorsal and anal fins. *Cololabis* lacks the anterior extensions of the jaws.

Sub-order 2. *Exocoetoidea*.—Scales rather large; mouth small. Third upper pharyngeals much enlarged, together forming a somewhat convex ovoid plate that opposes the concave upper surface of the broad lower pharyngeal. Cleithrum articulating directly with basioccipital. In the Hemirhamphidae, the premaxillaries form a flat triangular expansion in front, and the teeth in the jaws are small and compressed, generally tricuspid. These are coastal fishes of warm seas, said to feed mainly on green algae. Few exceed a foot in length. In *Hemirhamphus* the lower jaw is produced into a long pointed beak. In the Exocoetidae the premaxillaries are not expanded forwards, the teeth are minute, and the pectoral fins are much enlarged. The flying-fishes (*q.v.*), are found in the warmer parts of the oceans.

Order 13. *Microcyprini*.—Soft-rayed physoclists with abdominal pelvic fins, without lateral line, and with terminal mouth bordered above by the premaxillaries. Lower pharyngeals separate, or, if united, with persistent median suture. Parietals separated by supraoccipital; mesethmoid flat; nasals well separated; no orbitosphenoid.

The Amblyopsidae have a rather wide, non-protractile mouth, and vent jugular in position. The parietals are large, the opisthotic is well-developed, and the palatine and pterygoid bones are normal. These are fresh-water fishes of North America, *Chologaster* is normally pigmented and has small eyes. *Amblyopsis* and *Typhlichthys* are translucent, eyeless fishes with numerous tactile papillae on the skin, found in the subterranean streams of limestone regions.

In the Cyprinodontidae, or Poeciliidae the mouth is generally small and somewhat protractile, the parietals are small or absent, the opisthotic, if present, is small and adherent to the exoccipital, the palatine and ectopterygoid are ankylosed, and the metapterygoid is absent. The Fundulinae, oviparous and with conical teeth, are the most generalized and the most widely distributed group. There are numerous North American species, many marine and some confined to fresh-water, mostly belonging to *Fundulus*. *Rivulus* and *Cynolebias* are South American fresh-water genera, the latter remarkable for the difference between the sexes, the males having the dorsal and anal fins larger and formed of many more rays than the females. In Africa there are about 100 species, mostly confined to fresh water, belonging to *Nothobranchius*, *Haplochromis*, *Panchax*, etc., the last also occurring in southern Asia. *Haplochromis* ranges from India to Japan and Celebes. The Cyprinodontidae (*Cyprinodon* of North America, *Lebias* of the Mediterranean countries) have tricuspid teeth, and the Orestiinae, from elevated lakes in the Andes, differ from the Fundulinae in having no pelvic fins. The remaining Cyprinodonts are viviparous, and in relation to the development of viviparity it is interesting to note that courtship and pairing are general among the oviparous forms, in which the male is usually more ornamental than the female and may have enlarged and brightly coloured dorsal and caudal fins. Moreover in *Fundulus* it has been observed that the male closely embraces the female when she sheds the eggs.

In the Characodontinae the anal fin of the male has the first five or six rays short and stiff, separated by a notch from the rest of the fin. The subfamily is almost confined to the system of the Rio Lerma in Mexico. The seventeen species belong to four genera. The Jenynsiinae comprise the genus *Jenynsia*, with a few species from the La Plata and Argentina; in the male the urogenital duct is produced as a tube to the end of the anterior rays of the anal fin. In the Anablepinae, comprising *Anableps* with three species from Central and South America, the anal fin of the male and the produced tube are covered with scales and appear as a large, conical, scaly intromittent organ. *Anableps* is remarkable for having the eye divided by a transverse black band into an upper and a lower portion, the former raised above the surface of the head and used for vision in the air. The Poeciliinae have the anal fin of the male advanced and modified; the third, fourth

and fifth rays are enlarged and prolonged, and border a groove or tube into which the seminal duct opens; the prolonged rays may end in curved hooks or in antler-like processes, etc., the different modifications being of value in classification. Bony stays, projecting downwards and forwards from the posterior precaudal vertebrae, support the anal fin of the male. There are numerous species, all American, ranging on the coasts and in the rivers from the southern United States to the La Plata.

The Phallostethidae, little fresh and brackish-water fishes ranging from Singapore to the Philippines, differ from the Cyprinodontidae in having no pelvic fins and the vent placed just behind the head. The males have a large fleshy appendage, the priapium—below the head and chest—which contains the terminal parts and openings of the intestine, genital duct and ureters, and has a skeleton of its own, including a longitudinal bone, to which are articulated movable external bony appendages, an anterior, curved and pointed, the toxactinium, present only in *Phallostethus*, and one or two on one side near the posterior end, sometimes with serrated edge, and termed ctenactinia. The enlarged first pair of ribs extends downwards into the priapium and support it; it also contains longitudinal muscles that move the bony appendages, which are probably used to hold the female. The six species are referred to four genera.

Order 14. *Salmopercae*.—Physoclists with the dorsal and anal fins preceded by one to four spines and with sub-abdominal pelvic fins, each of a rudimentary spine and seven or eight soft rays; pelvic bones connected with post-cleithra. Premaxillaries forming upper border of mouth. No orbitosphenoid. Small fresh-water fishes of North America, including three genera, each with a single species, grouped into two families, Percopsidae (*Percopsis*, *Columbia*) with an adipose fin, and Aphredoderidae (*Aphredoderus*) without adipose fin, and with the vent at the throat in the adult. The head has large muciferous channels; those of the frontals are continued forwards in the large, thin, concave nasal bones, which nearly or quite meet in the middle line. This is an isolated order, without evident relationships except to the Isospondyli or primitive Iniomi.

Order 15. *Solenichthyes*.—Physoclists with abdominal pelvic fins without spine, and with the mouth at the end of a long tube-like snout. Parietals absent: pterotic extending downward to basioccipital; no opisthotic. A spinous dorsal fin sometimes present. This order includes six families, that may be classified as follows:—

I. Gills pectinate.

A. First four vertebrae very long, rigidly united, with transverse processes forming a continuous shelf; pectoral radials enlarged; mouth toothed; body very elongate (*Aulostomatoidea*).

Body scaly; a series of isolated dorsal spines . . . 1. *Aulostomatidae*.

Body naked; no dorsal spines . . . 2. *Fistulariidae*.

B. Anterior vertebrae long, but with separate transverse processes; pectoral radials small; mouth toothless; a spinous dorsal; body deep or moderately elongate (*Centriscoidea*).

Body with bony scutes and rough scales; caudal terminal . . . 3. *Macrorhamphosidae*.

Body encased in thin bony shields; spinous dorsal terminal; soft dorsal and caudal inferior. . . . 4. *Centriscidae*.

II. Gills lobate; mouth toothless (*Lophobranchii*).

A. Spinous dorsal, of flexible spines; pelvics large, seven-rayed; stellate ossifications on body; cleithrum attached to supracleithrum. . . . 5. *Solenostomidae*.

B. No spinous dorsal; no pelvic fins; body enclosed in bony rings; cleithrum attached to transverse processes of two first vertebrae. . . . 6. *Syngnathidae*.

Aulostoma coloratum, is the trumpet-fish of the Caribbean sea. *Fistularia* has three or four species from tropical seas. The Macrorhamphosidae, or snipe-fishes, include about 12 species from tropical and temperate seas. The Centriscidae (*Amphisilidae*) are very strongly compressed, with sharp-edged lower surface; four species are known from the Indo-Pacific. *Solenostomus* has a few species from the Indo-Pacific; in the female the pelvic fins form a pouch in which the eggs are carried. The Syngnathidae (pipe-fishes) are found in all warm seas, generally among sea-weeds; some enter fresh-water. The males carry the eggs in a groove or pouch, which in some genera is on the abdomen, in others under the tail. The dorsal and pectoral fins are small, but many rayed,

and locomotion is accomplished by their rapid undulating or vibrating movements; the caudal is small, or absent. The most interesting genus is *Hippocampus*, the sea-horses (*q.v.*), in which the horse-like head is set at an angle to the curved neck and can be moved up and down; the tail is prehensile, and by it these fishes attach themselves to sea-weeds; they swim and generally anchor themselves in a vertical position.

Order 16. **Anacanthini**.—Soft-rayed fishes with the pelvic fins often many-rayed, thoracic or jugular in position, but with the pelvic bones not directly attached to the cleithra. Caudal fin, when present, formed mainly of dorsal and anal rays, the homocercal fin being reduced. Air-bladder without duct. Mouth bordered above by the protractile premaxillaries. No orbitosphenoid; opisthotic large, extending downwards to basioccipital. A large and important group of marine fishes, carnivorous and with few exceptions living at the bottom, often at considerable depths.

Family Macruridae. The first vertebra articulates with the skull in the normal manner. The tail is long and tapering, without a caudal fin, and with the long dorsal and anal continued to its end. Large-eyed fishes, generally with a mental barbel, living at the bottom in deep water. The species are numerous.

Family Merlucciidae. First vertebra firmly attached to skull. Frontals separate, with ridges diverging from the occipital crest and bordering a large triangular depression. A short first dorsal and a long soft dorsal and anal; mouth wide, terminal, with strong teeth. *Merluccius* (hake, *q.v.*) with separate caudal fin, has three northern species, and three southern ones. *Macruronus* of New Zealand differs in having a tapering tail without caudal fin.

Family Gadidae. First vertebra attached to skull. Frontals united, without divergent ridges. A separate caudal fin. This large family includes a number of valuable food-fishes from northern seas. *Gadus*, with three dorsal and two anal fins, has the cod, haddock, whiting, pollack and coal fish (*qq.v.*) as its principal species. *Molva*, with two dorsal fins and one anal, and with strong teeth includes the ling (*q.v.*). *Lota*, the burbot (*q.v.*) of Europe, and North America, is the only fresh-water fish of the order. *Brosimius* (torsk), *Onos* (rocklings) are other important genera.

Family Muraenolepidae. *Muraenolepis* is an Antarctic genus apparently related to *Onos*, but differing in the restricted gill-openings, in having no separate caudal fin, etc.

Order 17. **Allotriognathi**.—Soft-rayed fishes (the first one or two rays of the dorsal sometimes spinous) with protractile maxillaries, each of an outer blade and an inner posterior process that is connected with its fellow and underlies the similar process of the premaxillary. Pectoral with horizontal base; pelvic fins, when present, below or a little behind the pectorals, often many-rayed; pelvic bones erect, triangular, inserted between hyopcoracoids and sometimes articulated to them. An orbitosphenoid, no opisthotic. This order includes marine, mostly oceanic, fishes, with large eyes, and with a rather small mouth, without or with feeble teeth. The families differ greatly, and their principal characters are shown in the following synopsis.

I. Body deep; dorsal and anal fins long. Skeleton well ossified; ribs strong. Epiotics separated by supraoccipital; post-temporal forked. No anterior cranial chamber; pelvics of 15 to 17 rays . . . 1. *Lampridae*.

A large anterior cranial chamber, the walls formed by the frontals, the floor by cartilage containing the mesethmoid and orbitosphenoid bones; pelvics of 8 or 9 rays. . . . 2. *Veliferidae*.

II. Body elongate; dorsal fin long; anal short or absent. Skeleton weakly ossified; ribs feeble or absent. Epiotics meeting behind supraoccipital; post-temporal a simple plate, overlying and firmly attached to parietal.

A. A cranial chamber as in *Veliferidae*. Eyes normal. Mouth moderately protractile; lower jaw short.

Pelvics close together, of one to nine rays. . . . 3. *Trachypteridae*. Pelvics, if present, widely separated, of five or six rays. . . . 4. *Lophotidae*.

B. No cranial chamber; frontals narrowed between orbits. Eyes telescopic, close together, directed forwards. Mouth extremely protractile; lower jaw very long. . . . 5. *Stylophoridae*.

The opah (*Lampris luna*) is the only species of its family. It is a large fish, reaching a length of five or six feet, plump, oval in

form, blueish with silvery spots and scarlet fins. *Velifer*, with two species from the seas of Japan and Australia, is more strongly compressed and has very high dorsal and anal fins. The Trachypteridae, or ribbon-fishes (*q.v.*), have a long and strongly compressed body; they are silvery, oceanic fishes. In the adult *Trachypterus* the lower lobe of the caudal fin is absent and the upper is turned upwards nearly at right angles to the body. *Regalecus* (oar-fish, *q.v.*) has the pelvic fins represented by a pair of long rays expanded at the ends. The Lophotidae resemble the Trachypteridae, but have a high crest on the head on to which the dorsal fin extends, beginning with a strong spine. *Stylophorus chordatus* of the tropical Atlantic is an extremely aberrant type, with large forwardly directed telescopic eyes, and with the lower lobe of the caudal produced into a whip that is twice as long as the fish itself. By a downward movement of the lower jaw the upper is pulled right away from the skull, and the mouth appears at the end of a membranous pouch; the downward projection would not catch the prey sighted by the forwardly directed eyes, and this is remedied by the head being thrown up as the mouth is protruded.

Order 18. **Berycomorphi**.—Physoclists with the anterior rays of the vertical fins spinous, with pelvic fins thoracic or subabdominal, often many-rayed and with caudal that has generally 19 principal rays, 17 branched. Mouth bordered above by the protractile premaxillaries; one or two supplemental maxillaries. Skull with orbitosphenoid, alisphenoids and Y-shaped "basisphenoid"; opisthotic well-developed; parietals separated by supraoccipital; a thin-walled otic bulla. Hyo-palatine and opercular bones normally developed. Vertebral centra solid and co-ossified with arches. Post-temporal forked, attached to epiotic and opisthotic; no mesocoracoid; pectoral radials hour-glass shaped, four in number. This order is distinguished from other physoclastic groups with many-rayed pelvic fins by the retention of many primitive characters. The presence of an orbitosphenoid and the normally developed opisthotic characterize the skull; the two supplemental maxillaries of the Berycidae and Holocentridae resemble those of the clupeoids and *Aulopus*; the caudal fin, except in the Polymixiidae, has the number of rays characteristic of the Isospondyli, and *Myripristis* has a toothed maxillary. The order appears to be directly intermediate between the clupeoid Isospondyli and the Percomorphi. Fossil berycoids are abundant in Cretaceous strata. Synopsis of the families:—

I. Pelvics subabdominal, 7 or 8 rayed, without spine. Caudal with 18 principal rays. A pair of hyoid barbels. Dorsal and anal long, with a few spines. . . . 1. *Polymixiidae*.

II. Pelvics thoracic, of a spine and 3 to 13 soft rays; pelvic bones attached to cleithra. No barbels.

A. Dorsal with few spines; abdomen not ridged.

Vertebrae 26–30. Maxillary exposed, behind the deep preorbital. . . . 2. *Berycopsidae*.

Pelvics 17–13. Vertebrae 24. Maxillary sheathed. . . . 3. *Berycidae*.

Pelvics 15, with laminar spine. . . . 4. *Diretmidae*.

Pelvics 15, with normal spine. . . . 5. *Caristiidae*.

B. Dorsal spines few; abdomen with a median series of ridged scales.

No subocular organ; scales normal; pelvics 16. . . . 6.

Trachichthyidae.

No subocular organ; scales large, bony, rigidly united; pelvics 13. . . . 7. *Monocentridae*.

An evertible subocular luminous organ. . . . 8. *Anomalopidae*.

C. A long spinous dorsal. . . . 9. *Holocentridae*.

All the Berycomorphi are marine, and except the Holocentridae, live in rather deep water. They are carnivorous, with bands of villiform teeth in the jaws. The Polymixiidae include the recent *Polymixia*, with species from the tropical Atlantic and Pacific, the Cretaceous *Platycormus*, and perhaps some less well known Cretaceous genera. *Berycopsis* is a Cretaceous genus. *Beryx* includes species from the north Atlantic and Japan, deep-bodied, large-eyed, reddish fishes with the anal fin much longer than the dorsal; it or both are preceded by three or four graduated spines. *Hoplopteryx* has the dorsal fin longer than the anal; it is preceded by six to eight spines, stouter and more spaced than in *Beryx*. There are several Cretaceous species, and four living in southern seas. *Diretmus argenteus* is a small and rare fish known

from near Madeira. The little-known Caristiidae include two genera each with a single species, *Caristius* from Japan and *Platyberyx* from the Atlantic. The Trachichthyidae include about 15 deep-water species belonging to *Hoplostethus*, *Trachichthys*, *Gephyroberyx*, etc. *Aipichthys* and *Acrogaster* are Cretaceous genera of this family. *Monocentris* is an Indo-Pacific genus with few species. *Anomalops* and *Protoblepharon* have a large luminous organ which can be everted or withdrawn into a cavity below the eye; each genus has a single species from the Malay archipelago. The Holocentridae, of which *Holocentrus* and *Myripristis* are the most important genera, include some 70 species from tropical seas, particularly abundant about coral reefs.

The Melamphaidae are oceanic fishes, found at considerable depths, which resemble the Berycomorphi in the structure of the protractile mouth, in the dorsal and anal fins with a few spinous rays, the caudal with 19 principal rays, 17 branched, and spinous procurent rays, and the pelvics thoracic, of a spine and six to nine soft rays. The Stephanoberycidae, are also deep-water fishes with a similar caudal fin; but they have no spines in the dorsal and anal fins, and have the pelvics abdominal, five or six rayed, without spine. These families have been associated in an order, Xenoberyces, but until their osteology is better known their position is uncertain.

Order 19. Zeomorphi.—Distinguished from the Berycomorphi by certain features of specialization. A spinous dorsal; anal fin preceded by one to four spines which form a more or less distinct fin; caudal with 12 or 13 principal rays; pelvics each of a spine and five to nine branched rays, thoracic. No orbitosphenoid. Post-temporal simple, rigidly united to skull; cleithrum ending above in a pointed projection just behind post-temporal. Pelvic bones directly attached to cleithra. First vertebra very firmly united to skull.

Two families, Zeidae with 31 to 46 vertebrae, and Caproidae with 22. The Zeidae include about 40 species from tropical and temperate seas, referred to 11 genera, *Zeus*, *Cyttus*, *Oreosoma*, *Grammicolepis*, etc. Most live in moderately deep water and have large eyes; they are deep strongly compressed fishes, with a very protractile mouth, which is suddenly projected to seize prey. *Zeus faber* is the John Dory (q.v.), which ranges from the Mediterranean to England. The Caproidae comprise two genera. *Capros aper* is the boar-fish, a small red fish with a very protractile mouth. In *Antigonia* the body is deeper and the mouth less protractile.

Order 20. Percomorphi.—Allied to the Berycomorphi, but without an orbitosphenoid, with not more than one supplemental maxillary; pelvic fins with not more than six rays, caudal typically with 17 principal rays, 15 branched, never with more. Pectoral arch attached to skull by a more or less distinctly forked post-temporal, and pelvic bones typically attached to cleithra, although in some groups this attachment is lost. Even after the exclusion of certain specialized offshoots as separate orders, this is a very large and diverse group, containing not only the typical perches (q.v.), but the mackerels, gobies, blennies (qq.v.), gray mullets (see MULLET), etc.

In the Berycidae the vertebrae number 24, 10 precaudal and 14 caudal. *Prolates* of the Upper Cretaceous, the earliest known perch, seems to have had the same number, as have several living Serranid genera. In several families of Percomorphi this number is constant, e.g., Lutianidae, Sparidae, Chaetodontidae, etc., and it is probable that this is a primitive percoid character derived from a berycoid ancestor.

SYNOPSIS OF THE SUB-ORDERS

Pelvic fins thoracic or jugular, typically of a spine and five soft rays; pelvic bones directly attached to cleithra; without special features characterizing remaining suborders. . . . 1. Percoidea.

Hyomandibular attached to suborbitals, with inner shelf articulating with prootic. . . . 2. Teuthidoidea.

Maxillary firmly attached to premaxillary, articulating with a prepalatine bone; pelvics of two spines and three soft rays between them. . . . 3. Siganoidea.

Ribs expanded juxtaposed rings enclosing the air-bladder. . . . 4. Kurtoidea.

Premaxillaries fixed, beak-like; hypurals not covered by bases of fin rays. . . . 5. Trichiuroidea.

Premaxillaries fixed; caudal widely forked, the bases of the rays of the upper and lower lobes meeting, concealing the hypurals. . . . 6. Scombroidea.

Opisthotic enlarged, reaching basioccipital; no parietals. . . . 7. Gobioidae.

No entopterygoid or metapterygoid; supra-cleithrum slender, directed outwards; pectoral radials large, laminar. . . . 8. Callionymoidea.

Pelvics jugular, with rays reduced in number; parasphenoid with ascending wings meeting alisphenoids or frontals; dorsal and anal rays corresponding to vertebrae, each basal attached to a neural or haemal spine. . . . 9. Blennioidea.

Pelvics jugular or mental, of one or two filamentous rays; fins without spines; parasphenoid meeting frontals; dorsal and anal rays more numerous than vertebrae. . . . 10. Ophidioidea.

Oesophagus expanded to form a muscular sac with internal papillae, and often with teeth. . . . 11. Stromateoidea.

An air-breathing chamber above the gills, containing a labyrinthic organ. . . . 12. Anabantoidea.

An air-breathing chamber above the gills; no labyrinthic organ; no spinous fin rays; pelvics subabdominal, six-rayed. . . . 13. Ophiocephaloidea.

Pelvics subabdominal, of a spine and five branched rays; pelvic bones not attached to cleithra; pectorals normal. . . . 14. Mugiloidea.

Pelvics subabdominal, of a spine and five branched rays; pelvic bones not attached to cleithra; pectoral with a detached lower part of free filamentous rays. . . . 15. Polynemoidea.

Within the limits of this article it is impossible even to mention by name, much less to define, all the families of the Percoidea, about 80 in number.

In the typical perches the spinous dorsal is well developed, and the pelvic fins are thoracic, each of a spine and five soft rays. The most generalized family is that of the Serranidae or sea-perches, which have pointed teeth, the maxillary exposed, the pelvic fins without a scaly axillary process, and the anal fin preceded by three spines. This large family includes carnivorous fishes that live at the bottom near the coasts in tropical and subtropical seas. *Epiniphelus*, *Serranus*, *Polyprion*, *Stereolepis* and *Morone* are important genera. To *Epiniphelus* and related genera belong the tropical sea-perches known as rock-fish, groupers (q.v.), etc. *Polyprion cernuum* is the wreck-fish of the Mediterranean and eastern Atlantic; *Stereolepis gigas*, the jew-fish (q.v.) of California, attains a length of seven feet and a weight of 500 lb. *Morone labrax*, the bass (q.v.), reaches the south coast of Great Britain; other species are American, two being fresh-water fishes. The Chilodipteridae differ from the Serranidae in having only two anal spines; these are small prettily coloured fishes; *Apogon* is the principal genus. The Latilidae include the tile-fish (q.v.), *Lopholatilus*, and the Sillaginidae are the sand-whitings of the Indo-Pacific; in both families the dorsal spines are slender. The Cirrhitidae and allied families are marine fishes with the lower pectoral rays simple and free at the tips.

The Centrarchidae are fresh-water fishes of North America. There are about 30 species, including the sun-fishes (*Lepomis*) and the black bass (*Micropterus*). The Percidae are fresh-water fishes of northern Eurasia and North America, with only one or two anal spines; British species are the perch (*Perca fluviatilis*) and the pope or ruffe (*Acerina cernua*). The pike-perches (*Lucioperca*) of North America and Europe are large predaceous fishes, valued as food. (See PIKE-PERCH.) The rivers of eastern North America are inhabited by a tribe of dwarfed Percidae known as "darters" (*Etheostoma*, etc.) of which more than 50 species are known, graceful little fishes that rest on the bottom and move with swift darts, propelled by their large pectoral fins. The Centropomidae have the maxillary exposed, and a scaly process in the axil of the pelvic fins. This family includes the large Nile perch, *Lates niloticus*, the robalos (*Centropomus*), silvery fishes found on both coasts of tropical America, and the Indo-Pacific *Ambassis*.

Several families of marine perches have a scaly axillary pelvic process, and the maxillary sheathed by the preorbital, namely the Lutianidae, or snappers, the Pomadasidae, or grunts, the Liognathidae, the Sciaenidae, or drums, the Mullidae, or red mullets, the Sparidae, or sea-brems, etc. Most are carnivorous fishes with conical teeth, but many of the Sparidae have blunt molars at the sides of the jaws, used for crushing shell-fish, and others with incisor-like teeth are herbivorous. The Mullidae have a pair of barbels at the chin, used to probe for the small shell-fish, worms, etc., on which they feed. The Sciaenidae, with a short

COMMON NORTH AMERICAN GAME FISHES

1. Lake Chautauqua muskallunge (*Esox ohienensis*). 2. Large-mouth black bass (*Micropterus salmoides*). 3. Brook trout (*Salvelinus fontinalis*). 4. Small-mouth black bass (*Micropterus dolomieu*). 5. Lake trout (*Cristivomer namaycush*). 6. Rock bass (*Ambloplites rupestris*). 7. Rainbow trout (*Salmo irideus shasta*). 8. Crappie (*Pomoxis annularis*). 9. Long-eared

sunfish (*Lepomis auritus*). 10. White perch (*Morone americana*). 11. Spotted catfish (*Ictalurus punctatus*). 12. Yellow perch (*Perca flavescens*). 13. Common pike (*Esox lucius*). 14. Eastern pickerel (*Esox reticulatus*). 15. Common silverside or shiner (*Notropis cornutus*). 16. Wall-eye pike-perch (*Stizostedion vitreum*)

spinous and long soft dorsal, make a drumming noise by the vibration of the air-bladder, which often bears a series of hollow branched appendages on each side. The *Pristolepidae* are freshwater fishes of India; *Pristolepis* is remarkable for having a very large patch of rounded molars in the roof of the mouth, borne by the expanded parasphenoid and opposed to a similar patch on the tongue. The *Hoplegnathidae* of the Pacific are allied to the *Lutianidae*, but have the teeth united to form sharp edged plates, as in the parrot fishes. The *Chaetodontidae* and related families are deep and compressed fishes with a small mouth furnished with bristle-like teeth; they are characteristic coral-reef fishes, often fantastically coloured.

The *Pomatomidae* are allied to the *Serranidae*, but have the spinous dorsal of a few short and slender spines, depressible in a groove, the soft dorsal, and anal long, pointed in front, and the caudal wide forked; the teeth are strong, compressed and acute. The blue-fish (*Pomatomus saltator*) is a large voracious fish found in all warm seas, swimming in shoals and attacking other fishes with great ferocity. The *Carangidae* resemble the *Pomatomidae* in fin structure, but have small teeth. This is a very large and varied family, found in all warm seas. *Naucratus ductor* is the pilot-fish (*q.v.*), *Seriola* includes the yellow-tails; in *Caranx*, etc., the scales of the lateral line form bony shields. Other percoids with widely forked caudal are the *Coryphaenidae* (dolphins) and *Bramidae*. The *Cichlidae*, with nearly 600 species from the fresh and brackish waters of tropical America and Africa, are typical perches allied to the *Serranidae*, but have a single nostril on each side, and the lower pharyngeals coalescent or united by suture, generally forming a triangular plate.

The percoids with the lower pharyngeals ankylosed to form a single bone form three distinct and apparently unrelated groups, two with a single family, the other with three.

The *Embiotocidae* are the surf-fishes of California and Japan, so-named because they mostly inhabit the surf along sandy beaches; they are viviparous. The *Pomacentridae*, with a single nostril on each side and with two anal spines, are small tropical marine fishes, often brilliantly coloured, and characteristic inhabitants of coral reefs. The *Labridae*, or wrasses (*q.v.*), are a large family of carnivorous marine fishes, in which the lower pharyngeals form a broad triangular or T-shaped plate, bearing conical or rounded teeth that bite against similar teeth on the enlarged upper pharyngeals. Most live in shallow water among rocks and weeds, and feed on shell-fish. The premaxillaries are protractile and the teeth in the jaws are separate. There are nearly 500 species. The tropical genera of *Julis*, *Platyglottis*, *Cheilinus*, etc., include a number of small and brightly coloured species. *Labrus* and related genera inhabit the north Atlantic. *Epibulus* of the Indo-Pacific has a very protractile mouth and is unique among fishes in that the quadrate is a long rod, articulated to the hyomandibular, its movement thrusting the lower jaw forwards.

The *Odacidae* of southern Australia and New Zealand resemble the *Labridae* in structure, but the premaxillaries are fixed, the teeth in the jaws are united to form low sharp-edged plates, and the pharyngeal teeth are pavement-like. *Siphonognathus*, with long tube-like snout, recalls *Fistularia* of the *Solenichthyes*. In the *Scaridae*, or parrot fishes (*q.v.*), the teeth in the jaws coalesce to form sharp-edged plates; the jaws are short and powerful, with the maxillaries firmly attached to the premaxillaries, and the dentaries movably articulated with the articulo-angulars. The pharyngeal teeth are flat, forming a pavement; the upper pharyngeals bear ridges above that move backwards and forwards in a pair of grooves on the parasphenoid, their teeth grinding against those of the lower pharyngeal, which occupy a quadrangular area. These are large-scaled herbivorous fishes of warm seas, especially abundant about coral reefs. More than 100 species are known, mostly beautifully coloured; some grow to a large size.

In the sub-order *Percoidea* are included a number of families that differ from the typical perches in having the pelvic fins jugular in position. The *Gadopsidae* include only *Gadopsis marmoratus* from the rivers of Australia, a perch-like fish with the pelvic fins reduced, each of a small spine and a bifid ray.

The *Ammodytidae*, or sand-launces (*see* SAND-EEL), are elongate fishes with a pointed head and long soft-rayed dorsal and anal fins; they burrow in the sand with great rapidity; *Ammodytes*, without pelvic fins, is a northern genus. In the remaining families with jugular pelvic fins these are formed of a spine and five soft rays; the spinous dorsal is short, the soft dorsal and anal are long. The *Trachinidae*, or weevers (*q.v.*), of the Atlantic coast of Europe and Africa, have grooved poison spines. The *Uranoscopidae*, fishes of warm seas, have a vertical mouth and the eyes placed on top of the head; they burrow in the sand, with only the eyes projecting, and attract small fishes by the play of a membranous flap or filament protruded from the mouth. The *Nototheniidae* and allied families are the characteristic fishes of Antarctic seas; they exhibit great diversity, some recalling the *Cottidae*, others the *Gadidae* of northern seas. The *Siganioidea* include the single genus *Siganus*, with about 30 species, herbivorous fishes of the Indo-Pacific, ovate and compressed in form, with small mouth and incisor-like teeth, with long dorsal and anal fins, each with several spines, and with the pelvics of two spines with three soft rays between them.

The *Teuthidoidea* include two families, the *Zanclidae*, with protractile premaxillaries and brush-like teeth, and the *Teuthidiidae*, with the small mouth formed as in the *Siganidae*, the maxillary being firmly united to the premaxillary, and the teeth incisor-like. The *Teuthidiidae* are herbivorous fishes of tropical seas. *Teuthis* (*Acanthurus*) has numerous species, known as surgeon-fishes, from the movable sharp-edged spine on each side of the tail.

The *Kurtoidea* include only *Kurtus indicus* of the Indo-Pacific, in which the expanded ribs enclose the air-bladder; it is a strongly compressed fish, with short dorsal fin and long anal; the males bear on top of the head a bony projection of the supraoccipital, curved forwards to form a hook, used for the attachment of the egg-masses, which these fishes carry about with them.

The *Trichiuroidea* are distinguished from the percoids by the non-protractile beak-like premaxillaries, to which the maxillaries are firmly attached; the pectoral fins are placed low. These are carnivorous marine fishes with large mouth, sharp teeth, and strong anterior canines. In the *Gempylidae* the body is elongate, the maxillary is exposed, and the pelvic bones are directly attached to the cleithra. In the *Trichiuridae* the body is very long and strongly compressed, the maxillary is sheathed by the preorbital, the caudal fin is small or absent, the pelvic fins, if present, are reduced to a pair of scale-like structures attached to a slender bone connected with the cleithra by a long ligament. The *Chiasmodontidae* comprise *Chiasmodon niger*, a small, blackish, bathypelagic fish of the Atlantic, which may be related to the *Gempylidae*. Specimens of *Chiasmodon* have been captured distended with fishes they have swallowed, sometimes many times their own size.

The *scombroidea* have the maxillaries attached to the non-protractile premaxillaries, which are typically produced and pointed. The caudal peduncle is slender, the caudal fin forked, with widely divergent lobes, and with the hypural covered by the bases of the rays. In these features the *scombroidea* are more advanced than the percoids, and it is remarkable that such highly specialized types as the sword-fishes (*q.v.*) should be known from Lower Eocene deposits. The *Scombridae* have beak-like premaxillaries and the pectoral fins placed high. This important family includes the mackerel, tunny, bonito, albacore (*qq.v.*), etc. They are carnivorous pelagic fishes, silvery and blue-backed, especially abundant in warm seas. The pointed head and fusiform shape mark them as swift swimmers; the spinous dorsal fin is formed of slender spines and is depressible in a groove; the soft dorsal and anal are composed of short anterior pointed portions, with the rays crowded together, followed by a series of detached and much branched rays, or finlets; in the oceanic species, such as the tunny, the pectoral and pelvic fins fold into depressions on the body, so as not to interrupt the contour.

The *Luvaridae* include a single species, *Luvarus imperialis*, a large pelagic fish with blunt head and small nearly toothless mouth, restricted gill-openings, and pectoral fins placed rather

low. The very large epiotics meet behind the supraoccipital and carry it forward to above the ethmoid. The Eocene *Semiothorax* has a scombroid tail and may belong to this group, but if the large pelvic fins have more than five rays its affinities may be elsewhere.

In the Histiophoridae (spear-fishes and sail-fishes) there is a long pointed rostrum, rounded in transverse section, formed by the united premaxillaries and by the nasals. The Xiphiidae (sword-fish) differ in that the rostrum is flat, sword-like. These families include large fishes of the warmer parts of the ocean, *Xiphias gladius* attaining a length of 20 feet. In the young both jaws are produced and the dorsal fin is high and continuous; this high fin persists in the adult *Histiophorus* (sail-fish) but in *Tetrapturus* and *Xiphias* it becomes low and divided. The Eocene Xiphiorhynchidae and Blochiidae are closely related to the Xiphiidae, the Blochiidae having long slender jaws like a young *Xiphias*. In all these the vertebrae number 24 to 26, but the Palaeorhynchidae, known from Eocene and Miocene deposits, had 50 to 60.

The gobioids are well distinguished from the percoids by the depressed skull, the absence of parietals, the enlarged opisthotic, and the large laminar pectoral radials. The spinous dorsal is formed of a few flexible spines, the anal is similar to the soft dorsal, the caudal is generally rounded. The group includes at least 600 species, mostly small, carnivorous, bottom-living, coastal fishes of tropical and temperate seas; several enter rivers, there are a number of species restricted to fresh water, especially in the Australian region. In the Eleotridae the pelvic fins are separate, and the pectoral radials are inserted on the hypercoracoid and hypocoracoid and on the fibrous or cartilaginous tissue between these bones. The largest of the group, reaching a length of two to three feet, belong to the genus *Philypnus*; these fishes, from the rivers of tropical America, somewhat resemble the pike-perches. Some eleotrids have a great likeness to *Ophiocephalus*. The Gobiidae differ from the Eleotridae in having the pelvic fins united to form an adhesive disc or cup, and in having the pectoral radials inserted on a ridge of the cleithrum, the hypercoracoid being absent. There are several British species of *Gobius* and numerous related forms in tropical and temperate seas, some on a sandy or muddy bottom, many in tidal pools, little fishes moderately elongate in form, with small terminal mouths furnished with conical teeth, and with large broad-based pectoral fins. *Aphya* and *Crystallogobius* are translucent pelagic gobies that live one year only. *Typhlogobius* of California is a naked pinkish fish with vestigial eyes hidden under the skin; it lives like a slug, fastened on to rocks or crawling about in the crevices. *Periophthalmus* and *Boleophthalmus*, mainly Indo-Pacific, but with one west African species, are distinguished by the large muscular lobes of the pectoral fins and by the prominent eyes, placed close together on top of the head; at low tide these fishes walk or jump about on the mud, hunting for food.

The Callionymoidea include the Callionymidae and Draconettidae, distinguished from the percoids by peculiarities of the skeleton of the head and pectoral arch; the vertebrae are compressed, and number 21 (7+14), the precaudals without ribs but with long epipleurals. These are small naked fishes with depressed head and small terminal mouth, living at the bottom in shallow or moderately deep water in tropical and temperate seas. The spinous dorsal is short, the pectorals are large, the pelvics are jugular in position. The Callionymidae or dragonets (*q.v.*), have a strong preopercular spine; in the Draconettidae the preopercle is unarmed, but the operculum and sub-operculum are reduced to a pair of strong spines. In *Callionymus* the males have large fins and bright colours; courtship and pairing has been observed.

The blennioids have the pelvic fins jugular or mental, each of a spine and four soft rays, or still further reduced. The parsphe-noid has strong ascending wings that meet the alisphenoids or frontals; the dorsal and anal rays correspond to the vertebrae, each basal bone being attached to its own neural or haemal spine. The most generalized family is that of the Clinidae, which are moderately elongate, generally scaly fishes, with a protractile mouth and conical teeth, and with a long spinous dorsal, one or

two anal spines, a separate caudal, broad-based pectorals and jugular pelvics, each of a spine and three or four unbranched rays, two or three of which are usually thickened and free distally. These are numerous species from tropical and temperate seas, especially California and South Africa, living near the coasts, often in rock pools or among weeds.

The Dactyloscopidae of the coasts of tropical America are related to the Clinidae. The Stichaeidae, Pholididae, Lumpenidae, etc., of arctic and northern seas, are elongate, with a long dorsal fin wholly or mainly formed of spines, and with the pelvic rays branched. The Zoarcidae are near the Clinidae; they are elongate fishes, with the long soft-rayed dorsal and anal fins joined to the caudal and with gill-openings restricted. Many, if not all, are viviparous, and most live in rather deep water. Most of the genera are arctic or northern, but the family extends down the Pacific coast of America to the Antarctic. *Zoarces viviparus* is the viviparous blenny. *Lycodes* is an important genus.

The Blenniidae, with the related Anarrhichadidae, Congrogadidae and Notograptidae, differ from the preceding families in having a stout, rigid suborbital ring firmly attached to the lateral ethmoid in front and to the frontal behind. In the Blenniidae the body is naked, the spinous and soft parts of the dorsal fin are generally equal, the pelvics are jugular, of a spine and two to four simple rays, and the mouth is non-protractile, the jaws have a single series of slender close-set teeth, within which is often a pair of strong curved canines, placed posteriorly. The main genera are *Blennius*, *Salarias* and *Petrosirtes*; there are numerous species from tropical and temperate seas, mostly small shore-fishes that shelter among rocks and weeds. *Xiphias* of the Indo-Pacific has the characters of *Petrosirtes*, except that the tail is very long and tapering, with the vertebrae and dorsal and anal rays much increased in number. The Anarrhichadidae have no pelvic fins, and the mouth is provided with strong conical canines in front and large molars at the side; these are large fishes of northern seas, belonging to two genera, *Anarrhichas* (wolf-fish, *q.v.*) and *Anarrhichthys* (wolf-eel).

The Ophidiioidea differ from the blennioids in that the dorsal and anal rays are closer together, their basals outnumbering the corresponding neural and haemal spines. There are no spinous fin-rays; the long dorsal and anal fins are generally confluent with the reduced caudal; the pelvics are close together each of one or two filamentous rays. The mouth is terminal, with bands of villiform or cardiform teeth. The first one or two ribs are expanded to support the air-bladder. There are three families, Brotulidae, Ophidiidae, and Fierasferidae. In the Brotulidae the pelvic fins are jugular, the parietals are separated by the supraoccipital and the opisthotic is not enlarged. This large family includes a great diversity of forms, some of the deep-sea genera being extremely aberrant. *Typhlonus* is eyeless, *Acanthonus* has a strong spine at the end of the snout, and *Lamprogrammus* has the lateral line enlarged and luminous. The blind cave-fishes, *Lucifuga* and *Stygicola*, of the subterranean rivers of Cuba are the only fresh-water fishes of the family; they are viviparous, and the new-born young have well-formed eyes, but these soon degenerate and become covered by the skin. The Ophidiidae differ from the Brotulidae in having the pelvic fins placed under the lower jaw, where they appear as a pair of forked barbels. *Ophidium* (cusk eel) and related genera are found in the Mediterranean and on the coasts of tropical America; *Gonypterus* is a southern genus. The Fierasferidae have no pelvic fins and the vent is jugular, although the skeleton is in most respects similar to that of the Brotulidae, it differs in that the parietals meet in the middle line and the large opisthotic reaches the basioccipital. These are little eel-like fishes of warm seas that often live inside holothurians, or in the shells of living oysters.

The stromateoids differ from the percoids in that the oesophagus is expanded to form a sac with muscular walls, internally covered with papillae that bear setiform teeth in the Nomeidae and Stromateidae, but not in the Tetragonuridae. These fishes have a single series of small teeth in the jaws and are mostly oceanic, feeding on pelagic crustaceans, medusae, etc. The Nomeidae include the black-fish, *Centrolophus niger*. *Nomens gronovii*, a little

fish found in all warm seas, with very large pelvic fins that fold into a groove on the abdomen, swims in small companies under a *Physalia* (Portuguese man-of-war), unharmed by its stinging tentacles. The Stromateidae are deep and strongly compressed in form. *Persilus triacanthus*, the butter-fish of the Atlantic coast of North America, is valued as food.

The anabantoids have an air-breathing chamber above the gills containing a labyrinthic organ, the folding of which increases the respiratory surface. They are fresh-water fishes of Africa and southern Asia, perhaps related to the Nandidae. The Anabantidae include *Anabas scandens*, the so-called "climbing perch," famous for its journeys on land, *Osphromenus* (gourami), *Polyacanthus* (paradise-fish), *Betta* (fighting-fish), etc. The Ophiocephaloids are generally considered to be related to the Anabantidae, as they have an air-breathing chamber above the gills, but this is a diverticulum of the pharynx, not of the gill-chamber, and contains no labyrinthic organ. *Ophiocephalus* of Africa and tropical Asia includes species that are elongate in form, with broad flattish head covered with large scales, rather large mouth with pointed teeth, long soft-rayed dorsal and anal and subabdominal six-rayed pelvic fins. These fishes are piscivorous; some reach a length of two feet; when the ponds dry up they either burrow in the mud or migrate overland; they are unique among fresh-water fishes in having floating eggs, laid in a round space cleared among the reeds by the male who guards them.

The Mugiloidea have a separate spinous dorsal and subabdominal pelvic fins, each of a spine and five branched rays. There are three families, Sphyraenidae, Mugilidae and Atherinidae. The Sphyraenidae or barracudas, are pike-like fishes of tropical seas, with strong acute sharp-edged teeth; some reach a length of eight feet. The Mugilidae, or gray mullets, have a small mouth, with the teeth in bands, or in *Mugil* reduced to a series of minute bristles; they are found on the coasts of all tropical and temperate countries; some species enter fresh-water. *Mugil* includes about 100 species; these fishes swim in large shoals and feed mainly on mud. The Atherinidae, or sand-smelts, differ from the Mugilidae in having 32 to 60 vertebrae, instead of 24 to 26; they are small silvery carnivorous fishes that frequent inlets and often enter fresh water; nearly 100 species are known. *Chirostoma* has about 20 species from the lakes of the Valley of Mexico. *Melanotaenia* and related genera inhabit the rivers of Australia and New Guinea. The Polynemidae resemble the mugiloids in external characters, except that the lower rays of the pectoral are detached and produced into filaments, used as feelers. The shoals frequent sandy bays and estuaries in the tropics.

Order 21. **Scleroparei**.—Allied to the Percomorphi, but with the second suborbital produced across the cheek, typically articulating with the preoperculum. The recognition of this large and varied group as an order is convenient. The most generalized family, the Scorpaenidae, is not very remote from the Serranidae. The families may be arranged thus:—

I. Mesethmoid ossified; nasals paired; an opisthotic. Second suborbital rigidly attached to first. Post-temporal not enlarged. Anterior vertebrae free, normal.

A. Pelvic bones directly attached to cleithra. (Scorpaenoidae).
1. Opisthotic large; post-temporal forked; palatine and pterygoids normal.

a. Vertebrae 24–40; anterior ribs sessile.

3 pairs of toothed upper pharyngeals. . . . *Scorpaenidae*, *Triglidae*, *Caracanthidae*.

1 pair of toothed upper pharyngeals. *Aploactidae*, *Synanciidae*, *Pataecidae*.

b. Vertebrae 42–64; ribs on strong parapophyses. *Hexagrammidae*, *Anoplopomatidae*.

c. Vertebrae 27; ribs attached to sessile epipleurals. *Platycephalidae*.

2. Opisthotic large; palatine and ectopterygoid united to form a slender rod; no entopterygoid. *Hoplichthyidae*.

3. Opisthotic large; post-temporal simple, an integral part of skull. *Congiopodidae*.

4. Opisthotic small; entopterygoid reduced.

a. Pelvic fins normal; body naked or scaly. *Cottidae*, *Cottunculidae*, *Psychrolutidae*, *Comephoridae*.

b. Pelvics normal; body enclosed in bony rings. *Agonidae*.

c. Pelvics forming a sucker. *Cyclopteridae*.

B. Pelvic bones not attached to cleithra (*Gastrosteoidea*). . . .

Gastrosteidae, *Aulorhynchidae*.

II. Mesethmoid unossified; nasals united to form a median plate; no opisthotic. Second suborbital small, movably articulated with first and with preoperculum. Post-temporal a very large plate. First three vertebrae long, rigidly united. Pelvic bones attached to cleithra. Pectoral fin very large. (*Dactylopteridae*). *Dactylopteridae*.

The Scorpaenidae include some 300 species from tropical and temperate seas, but are especially abundant in the north Pacific. They are carnivorous, bottom living fishes, some with a mottled coloration that matches the rocks and weeds among which they live, others from deeper water reddish in colour. The spinous dorsal is well-developed, and the lower pectoral rays are simple, often free at the tips. In *Sebastes* and related northern genera the vertebrae number more than 24. *Sebastes marinus* is the "Norway haddock," a reddish fish found on both sides of the north Atlantic; it reaches three feet in length and is viviparous. *Scorpaena*, with numerous tropical species, has 24 vertebrae; the head is spiny and there are little skinny flaps on the body. *Pterois* is an Indo-Pacific genus; the pectorals are much enlarged and the dorsal spines are very long and inflict poisonous wounds.

In the Triglidae or gurnards (*q.v.*), the three lowest rays of the pectoral fins are detached to form long finger-like appendages, used for crawling about on the bottom, or for turning over the sand or gravel in search of worms, crustaceans, etc., on which these fishes feed. There are several European species of *Trigla*, which is also found with *Lepidotrigla* in the Indo-Pacific. *Prionotus* has about 20 American species. *Peristedion*, covered with bony plates and with only two detached pectoral rays, is a deep-water genus. The Caracanthidae are little fishes of the Indo-Pacific, oval and compressed in form. The Synanciidae of the Indo-Pacific include *Synanceia* and related genera, naked, with vertical mouth and with poisonous dorsal spines; they lie in crevices in the reefs. *Pataecus* from temperate Australia has a grotesque appearance; the dorsal fin extends forward on the head, which has a vertical profile.

The Hexagrammidae and Anoplopomatidae of the north Pacific form a group apart, distinguished by the numerous vertebrae, the many rayed dorsal and anal fins, the small scales, etc.

In the Platycephalidae the head is broad and flattened; there are about 50 species from the Indo-Pacific. The Hoplichthyidae resemble them in the form of the head, but structurally are quite different. The Congiopidae include *Congiopus*, with a few species from Chile, South Africa and Australia and *Zanclorhynchus*, with one species from Kerguelen; the snout is produced, and the mouth is small. In *Congiopus* it has been observed that the naked skin grows very thick and becomes dirty-brown in colour and is then cast off in patches, revealing the bright new skin underneath.

The Cottidae comprise some 300 species from northern seas and a few fresh-water forms from Europe, northern Asia and North America. They are known as sculpins and bullheads (*q.v.*). The majority are small fishes, rather sluggish in habit. *Cottus gobio* is the bullhead or miller's thumb of the rivers of Europe. *Myoxocephalus scorpius*, the sea-scorpion of the north Atlantic, reaches a length of two feet. The Psychrolutidae and Cottunculidae are degenerate deep-water cottids. The Agonidae are armoured cottids. There are about 50 species, small fishes, all from northern seas except one from Patagonia.

The systematic position of the Gastrosteidae, or stickle-backs (*q.v.*), is uncertain, but the second suborbital extends across the cheek to the preoperculum in the typical scorpaenoid manner, and they have no characters that negative this idea of their relationship. They differ from the scorpaenoids especially in that the pelvic fins are sub-abdominal and the pelvic bones are not attached to the cleithra, and in the presence of a pair of large dermal plates that fuse with the hypocoracoids. The body is naked, with or without a series of bony plates, the dorsal spines are isolated and the pelvic spines are strong. *Gastrosteus aculeatus*, the three-spined stickleback, ranges from the Arctic seas southward to California and southern Europe; in the greater part of its range it is both marine and fresh-water, but southwards is not found in the sea. The marine forms generally have a complete series of bony plates, which are best developed in the colder seas; in fresh water the plates are absent except just behind the head and near the end of the tail. *Pygosteus pungitius*, the ten-spined stickleback, has many local forms in the rivers of Europe, northern Asia and North

America; northwards it enters the sea. *Apeltes* and *Eucalia* are American genera, and *Spinachia* is the fifteen-spined stickleback of the seas of Europe. The sticklebacks are remarkable for their voracity and pugnacity and for the nest-building habits of the males, who protect the eggs and young.

The Aulorhynchidae, with tubiform snout and ribs supporting the lateral bony plates, comprise two species from the north Pacific. The Dactylopteridae differ very markedly from the scorpaenoids. The arrangement of the suborbitals gives free play to the long spine with which the preoperculum is armed. There are four species from tropical seas, belonging to two genera, *Dactylopterus* and *Dactyloptena*. The pectoral fins are used for flight, which is less sustained than in the flying-fishes (Exocoetidae).

Order 22. **Hypostomides**.—Body enclosed in a broad bony box, tail in bony rings; a rostrum formed by the coalesced nasals; behind it a bony cavity bounded by the nasals and preorbitals, open below and containing the mouth, which is small, toothless, and protractile downwards; maxillaries protractile, produced forwards above premaxillaries, meeting in front and connected by ligament to roof of bony cavity; premaxillaries retractile within maxillaries. No alisphenoids or opisthotics. No entopterygoid or metapterygoid; palatine and ectopterygoid unconnected with quadrate. Post-temporal an integral part of skull; no supra-cleithrum; pectoral fins large, horizontal; pelvics abdominal, of a spine and one or two long unbranched rays; pelvic bones large, connected with cleithra by ligaments; no spinous dorsals, 19–34 vertebrae (7+12–15) the first six immovably joined. No air-bladder. The Pegasidae are curious little fishes from tropical seas, the systematic position of which is quite uncertain.

Order 23. **Heterosomata**.—Allied to the Percomorphi, but asymmetrical, with both eyes on one side. Strongly compressed fishes, with long many-rayed dorsal and anal fins.

The flat-fishes differ from all other fishes in their asymmetry; they live at the bottom, with the eyed side, which is coloured, uppermost, and with the blind side, which is generally white, underneath. When they are first hatched the larvae have the eyes on opposite sides and swim near the surface in the normal manner, but at an early age one eye migrates round the top of the head to the other side and thenceforth the fish lives at the bottom, eyed side up. Williams (*Bull. Mus. Comp. Zool.* 1902), has studied the migration of the eye; in the cartilaginous skull of the larva two bars above the eyes connect the lateral ethmoid cartilages with the otic capsules; preparatory to the migration of one eye the bar above it is resorbed and becomes reduced to projections of the lateral ethmoid and otic capsule with a gap between them. Through this gap the eye migrates until it reaches the other supra-orbital bar, when both eyes move to their final position, causing a torsion of the bar between them which also affects the ethmoid region; when the shifting is complete ossification takes place, and the main part of the frontal bone of the blind side forms on the wrong side of its eye. Thus the essential feature of the skull of the flat-fishes is that the interorbital bar is formed mainly by the frontal of the eyed side and that the frontal of the blind side extends forward to the ethmoid region outside the upper eye.

A peculiarity of the flat-fishes is that they are able to raise their eyes and move them independently, so that they can survey the ground round them. Another peculiarity, which has already been referred to, is their power of changing their coloration to resemble the ground on which they lie. In certain species albinos, partial albinos, etc., are fairly common, but the most interesting variation is known as ambicoloration, the blind side being coloured as well as the eyed side. Ambicoloration may be incomplete, the fish having irregular spots on the blind side, or having part coloured like the eyed side and the rest white; frequently it is complete except for a white patch on the head in the orbital region, which is the first and most asymmetrical part of the fish. When ambicoloration is complete or nearly so it is always associated with other variations towards symmetry, the scales of the blind side assuming the structure of those of the eyed side and the migration of the eye being delayed so that it reaches only the top of the head and interferes with the growth forward of the dorsal fin, which forms a hook above it.

Reversal, the occurrence of individuals with the eyes and colour on the side which is generally eyeless and white in the species is not uncommon; indeed, in some species of *Paralichthys* from the Pacific coast of America reversed specimens (with eyes on the right side) are as numerous as the normal ones. The researches of Parker on the optic nerves (*Bull. Mus. Comp. Zool.* 1903) are of great interest in this connection. In fishes generally the optic nerves cross each other, and the left crosses above the right as frequently as the right above the left. This has been found to be true of the soles, whether dextral or sinistral, and of *Psettodes*, the most primitive living flat-fish, and it follows that in these the nerves are partly uncrossed when that of the migrating eye is above the other and are nearly doubly crossed when it is below it. But in other flat-fishes, whether dextral (*Pleuronectes*, etc.) or sinistral (*Paralichthys*, etc.), Parker has found that the nerve of the migrating eye is always above the other, except in reversed examples, in which that nerve is dorsal which is normally dorsal in the species.

The flat-fishes are a large and varied group, and may be divided into five families. The Psettodidae include the single genus *Psettodes*, with two species, one west African, the other ranging from east Africa to China. Except for its asymmetry and the long dorsal and anal fins *Psettodes* is a typical perch and might almost be placed in the Serranidae. The combination of 24 vertebrae (10 precaudal and 14 caudal), 17 principal caudal rays, 15 branched, and pelvic fins of a spine and five soft-rays, with the pelvic bones directly attached to the cleithra, is common among the percoid fishes but is not found in any other group. In *Psettodes* alone among the flat-fishes the dorsal fin has anterior rays with slender spines and does not extend forward on the head. *Psettodes* has a larger mouth than any other flat-fish and the teeth are strong and pointed; it probably lies concealed at the bottom and makes short dashes after fishes that come near. It may have retained so many percoid features because it has not adopted progression along the bottom by undulating movements of the body and marginal fins to the same extent as other flat-fishes. In the remaining members of the order the dorsal fin extends forward on the head at least to above the eye, all the fin-rays are articulated, and the vertebrae are never fewer than 28.

The Bothidae are sinistral, with the nerve of the right eye dorsal. The mouth is terminal, with the lower jaw prominent, and the jaws and teeth are usually equally developed on both sides. There are three sub-families, the Paralichthinae, in which both pelvic fins are short-based, the Bothinae, in which the pelvic fin of the eyed side extends forward and is supported by a plate of cartilage; the third is the Psettinae, in which both pelvic fins are elongate and supported by cartilaginous plates. The first two sub-families include about 30 genera from tropical and temperate seas, none of which, except *Paralichthys*, includes fishes of great value as food. The Psettinae of the north Atlantic and Mediterranean include the turbot (q.v., *Psetta maxima*) and the brill (*P. laevis*).

The Pleuronectidae are dextral, with the nerve of the left eye dorsal; the mouth is terminal, with the lower jaw prominent. There are four sub-families, Pleuronectinae, Paralichthodinae, Samarinae and Rhombosoleinae, of which the first and last are important. In the Pleuronectinae the pelvic fins are short-based. This sub-family includes a number of genera from Arctic and northern seas. Of those with the mouth large and the jaws and teeth equally developed on both sides the most important is the halibut (q.v., *Hippoglossus*) which reaches a length of over eight feet, a voracious fish and an active swimmer, with the body thicker and more elongate than in most flat-fishes. The genera with a small asymmetrical mouth, with the jaws and teeth more developed on the blind side, include *Limanda* (dab) *Pleuronectes* (plaice, q.v.) *Microstomus* (lemon-sole) and *Glyptocephalus* (witch). These feed at the bottom of the sea on shell-fish and other invertebrates.

In the Rhombosoleinae the pelvic fin of the eyed-side is median, elongate, often continuous with the anal and with the rays increased in number. The jaws of the blind side are strongly curved and toothed, those of the eyed side toothless. The principal genera are *Rhombosolea*, *Peltorhamphus* and *Ammotretes* from south-

ern Australia and New Zealand, with *Oncopterus* from Patagonia.

The remaining members of the order are grouped together as soles (*q.v.*), distinguished by having the mouth small, with the lower jaw not prominent, and with the jaws of the blind side strongly curved and toothed, by having no free preopercular margin, by the absence of ribs, etc. In spite of these characters in common it is doubtful whether the two families, the dextral Soleidae and the sinistral Cynoglossidae, are very closely related.

The Soleidae, or true soles, include over 100 species from the sandy shores of tropical and temperate seas; many enter rivers and there are a few permanently fluviatile forms. The eyes are small, the lower surface of the head generally bears tactile filaments and the under nostril is frequently greatly developed. Probably the majority are not unlike the common sole of Europe (*Solea vulgaris*) in their habits; this species generally lies hidden in the sand by day and at night feeds on invertebrates, small fishes, etc., that it finds by smell and touch. The American soles (*Achirus*) are distinguished by the elongation of the pelvic fin of the eyed side, which is joined to the anal. *Synaptura* is a large genus, which like *Solea* ranges from the eastern Atlantic throughout the Indo-Pacific.

The Cynoglossidae or tongue-soles are sole-like fishes with eyes on the left side, vertical fins confluent, no pectorals, and the pelvic fin of the blind side median, that of the eyed side being displaced and reduced. These are slender fishes, with rounded head and tapering tail, from warm seas. Principal genera, *Symphurus*, *Paraplagusia*, *Cynoglossus*.

Order 24. **Discocephali**.—Allied to the Percomorphi, but with the spinous dorsal fin transformed into a flat, oval, transversely laminated, adhesive disc, which extends forward on the upper surface of the head. The spinous fin-rays are shortened, depressed backwards, divided into their two components, and expanded transversely to form pairs of broad flat laminae that are denticulated near their free posterior edges; in the middle line, pointed posterior projections of each pair of laminae are connected by ligament, and are joined to those of the next pair by a low fin-membrane. The small lateral expansions of the radials found in the spinous dorsal of most percoids have developed into large overlapping laminae; the basals are nearly normal, except that they are directed very obliquely backwards.

The Echeneidae include about 10 species belonging to genera, *Echeneis* and *Remora*. The largest species, *Echeneis naucrates*, attains a length of about three feet. They are carnivorous fishes of warm seas, attaching themselves to sharks or other marine animals, or to floating objects. By slightly raising the laminae of the suction disc a series of vacuum chambers is created; to dislodge a sucker-fish from an object to which it adheres it is pulled forwards, depressing the laminae; if it be pulled backwards the laminae are raised, and the harder the pull the more firm becomes the attachment. This is well known to the fishermen who in different parts of the world use these fishes to catch turtles. In pelagic percoids and scombroids the spinous dorsal fin is generally formed of short or slender spines and is depressible in a groove. Some of these, such as the pilot-fish (*Naucreates*) associate with sharks, and it seems not unlikely that some such fish should have found that the spinous dorsal fin, if depressed in its groove and then slightly raised, could be used more or less effectively as an adhesive organ, and should have acquired the habit of fastening on to its protector; the development of the adhesive disc would have followed. In the Echeneidae the disc is nearly as broad as the head, extends forwards to the snout, and is formed of 10 to 30 segments. In the Upper Eocene *Opisthomysom* the disc was narrow, about a third as broad as the head, short, being restricted to the postorbital part of the head, and formed of about six segments, in which the median projections of the laminae were relatively strong and seem to have been undivided. The broad opercles and the widely forked caudal indicate that this was a more active swimmer than its modern relatives.

Order 25. **Plectognathi**.—Allied to the Percomorphi. Parietals absent, or co-ossified with epiotics, which are separated by supra-occipital; hyomandibular and palatine rigidly united to skull;

post-temporal short, simple, completely united by suture to pterotic; pelvic bones, when present, long, united by suture or co-ossified. Gill-openings small.

Fishes of warm seas, generally with bony or spiny scales, a small mouth with short but powerful jaws, and the teeth usually strong incisors or forming a sharp-edged beak. Except in the Triacanthidae, the premaxillaries are not protractile and the maxillaries are firmly attached to them. There are seven well defined families, which may be grouped into two sub-orders. The plectognaths are worthless as food, and many are poisonous.

Sub-order 1. **Balistoidea**.—Supra-cleithrum vertical. Pectoral radials small, movable. Neural spines single. The Triacanthidae have a deep compressed body covered with small rough scales, a small mouth with a few strong teeth and with the upper jaw protractile, a spinous dorsal fin with the first spine strong, and the pelvic bones firmly attached to the cleithra and supporting the strong pelvic fin-spines, each of which has an inner basal knob that locks it when everted. *Triacanthus* comprises about eight species from the Indo-Pacific; silvery blue-backed fishes with two series of teeth, the outer incisors, the inner blunt; they live on a sandy bottom and feed mainly on shell-fish. In the other genera the teeth are conical. *Halimochirus* of the Indian ocean, a deep-water fish, is remarkable for the long tubiform snout.

In the Balistidae the maxillaries are firmly attached to the non-protractile premaxillaries, the mouth is small, with incisor-like teeth in a double series in the upper jaw and a single series in the lower, the first dorsal spine is strong and when erected is locked by a knob on the second, the pelvic bones are co-ossified to form a long bone, movably attached to the cleithra, helping to expand an abdominal air-sac, and the pelvic fins are represented by a short spine at the end of the pelvis. There are about 100 species from tropical and sub-tropical seas. The most important genera are *Balistes* (the trigger-fish), covered with juxtaposed bony plates, and *Monacanthus* (the file-fish) covered with close-set spinules. Species of *Balistes* are said to eat pearl-oysters, first making a hole in the shell with their teeth.

Triodon bursarius of the Indian ocean is the single species of the family Triodontidae, which resembles the Balistidae in having the pelvis a long movable bone that dilates the air-sac, but differs in having no spinous dorsal fin and in having the teeth represented by a beak. The Ostracodontidae, or trunk-fishes, differ from the Balistidae in that the scales are hexagonal bony plates, united to form a firm box that encloses the head and body, except for the small mouth and the short, naked tail. There is no spinous dorsal fin and no pelvis. There are about 25 species from shallow coastal waters of warm seas. Genera, *Aracana*, *Ostracion*, *Lactophrys*.

Sub-order 2. **Tetrodontoidea**.—Supra-cleithrum oblique or horizontal. Pectoral radials enlarged, fixed. Neural spines of anterior vertebrae double. Teeth in jaws enlarged or united to form a beak. No spinous dorsal. No pelvis or pelvic fins. In the Tetrodontidae the tooth-plates of the jaws are divided in the middle, and the palatines are united by suture to the mesethmoid. They are naked fishes, generally with movable spines in the skin, and have a large sac connected with the oesophagus which they can distend with either water or air until the fish is blown out like a balloon and the spines on the skin are erect. There are over 100 species, mostly marine and tropical but a few confined to fresh water. In *Lagocephalus* the nostrils are normal, in *Spheroideus* they are borne on a tubular papilla, the interior of the tube representing the nasal sac; in other genera the nostrils are confluent so that the tube has a single terminal opening with two lips; finally in *Tetrodon* the tube is very short and its lips appear as a pair of tentacles united at the base.

The Diodontidae differ from the Tetrodontidae in having undivided tooth-plates, with crushing surfaces developed within, and in having the palatines united by suture to the frontals, this feature being related to the fact that the head is broad and the snout very short, with the mesethmoid reduced. The spines are stronger than in the Tetrodontidae, in some species two-rooted and movable, in others three-rooted and fixed.

The Molidae are more primitive than the two preceding

families in having gills on all four branchial arches instead of on three only. In their osteology they are very similar to the Tetraodontidae, but the teeth form an undivided beak, as in the Diodontidae. The body is truncated immediately behind the dorsal and anal fins, with a deep caudal fin extending along its posterior end. These are oceanic fishes, found in the warmer seas, often seen at the surface. *Ranzania* includes a single species, oblong in form, with the skin tessellated with hexagonal plates, *Mola* has two species, deep and broad fish with a rough skin, which reach a length of over eight feet. The larvae of *Mola* acquire an armature of spines, and when only 5 mm. long, five of these have grown out into long horns, one on the snout, one on the back, one on the chest, and one on each side of the body. The fish loses the end of its tail and becomes very deep in form, the spines get shorter and a new caudal fin develops connecting the dorsal and anal; thus at a length of 15 mm., it has the general characters of the adult fish, except for the presence of a number of small conical spines.

Order 26. **Malacichthyes**.—Physoclists with the mouth bordered above by the non-protractile premaxillaries, without spinous fin-rays, and with pelvic fins, when present, sub-abdominal, five-rayed. Skeleton weakly ossified, soft, largely cartilaginous; a complete cartilaginous cranium, with the cartilage bones mostly well-separated; no orbitosphenoid and no opisthotic; membrane bones thin; parietals separated by supraoccipital. Post-temporal simple, the lower fork represented by ligament; pectoral radials on the cartilage separating the coracoid ossifications; pelvic bones small, remote from the cleithra. Vertebrae numerous (70); ribs feeble; hypurals radiating.

The position of these fishes is uncertain, but they may be specialized and degenerate percoids. The single family, Icosteidae, comprises the monotypic genera *Icosteus* and *Acrotus*, from deep water off the Pacific coast of North America. They are ovate and strongly compressed, with long many-rayed dorsal and anal fins, slender caudal peduncle and fan-shaped caudal fin; the mouth is terminal; the teeth are small, pointed, uniserial.

Order 27. **Xenopterygii**.—Allied to the Percomorphi. Naked fishes, with broad head, pointed snout, and small mouth with conical or incisor-like teeth in the jaws; body depressed, tail short. No spinous dorsal. A large subcircular adhesive disc on lower surface of abdomen, surrounded by a fold of skin, which anteriorly is supported by the rays of the widely separated pelvic fins and posteriorly by the lower edges of the post-cleithra, the upper of which is a broad free plate, from which the lower runs across to meet its fellow in the middle line. Entopterygoid and metapterygoid absent; ectopterygoid vestigial, attached to quadrate. Ribs attached to the ends of sessile epipleurals. Post-temporal simple, rod-like, directed outwards, at right angles to the backwardly directed supracleithrum. The cling-fishes, Gobiesocidae, are small carnivorous fishes of tropical and temperate seas, living near the coasts, adhering to stones or shells, and feeding on small invertebrates. Most of the species are red in colour.

Order 28. **Haplodoci**.—Distinguished from the Percomorphi by peculiarities of the skull and of the pectoral arch. First vertebra rigidly attached to skull, which is broad and flat; epiotics and opisthotics absent; post-temporal short, simple, united to skull by suture; hypercoracoid and hypocoracoid small; pectoral radials elongate, four or five in number, the lowest much expanded distally. No ribs, but epipleurals present. Gill-openings restricted. This order includes the single family Batrachoididae, fishes with elongate body, depressed head and wide terminal mouth, with conical or cardiform teeth in the jaws and on the palate. There is a spinous dorsal fin of two to four sharp spines, and a long soft dorsal and anal; the pectorals are broad-based, the pelvics jugular, of a spine and two or three soft rays. The toad-fishes, of which about 20 species are known, inhabit tropical and sub-tropical seas, living on the bottom in shallow or moderately deep water. They feed on crustaceans, molluscs and small fishes. *Porichthys*, with rows of silvery spots on the body, produces a humming sound by the vibration of the air-bladder. This is an American genus, as is *Thalassophryne*, in which the spines of

the dorsal fin and operculum are hollowed to transmit the venom contained in little sacs at their bases.

Order 29. **Pediculati**.—Distinguished by having the spinous dorsal fin formed of a few flexible rays, the first of which (the *illicium*) is placed on the head, generally ends in a flap, tassel or bulb, and is used as a line and bait. Pectoral arch as in the Haplodoci; but only 2 or 3 radials; skull differing especially in having particularly well-developed epiotics, which meet behind the supraoccipital. No ribs and no epipleurals. Gill-openings small.

Sub-order 1. **Lophioidea**.—This includes the single family Lophiidae, with about 20 species, naked fishes with a large depressed head and a wide mouth, with depressible cardiform teeth in the jaws. Pelvic fins are present, jugular, each of a spine and five soft-rays. The lower pharyngeals are well developed and toothed. *Lophius piscatorius* is the angler-fish (*q.v.*) or fishing-frog of the north Atlantic; it lives on the bottom down to depths of 200 fathoms, and lies in wait for its prey, attracting them by movements of the flap at the end of the illicium. A second species of *Lophius* is known from Japan. The tropical genera have fewer vertebrae and a shorter tail; some species, *e.g.*, *Chirolophius neresii*, are remarkable for the branched tags that project from the body, giving the fish the appearance of a stone with weeds on it.

Sub-order 2. **Antennarioidea**.—This sub-order includes anglers in which the mouth is small, or of moderate size. They resemble the lophioids in having pelvic fins and toothed lower pharyngeals, but differ in the structure of the vertebral column and skull, particularly in having the frontal bones separated for the greater part of their length. The Antennariidae are small fishes, compressed in form, with three fin-rays on the head; they are known as sea-toads or frog-fishes. Numerous species of *Antennarius* inhabit the tropical seas; they have a prickly skin and are often coloured with bright markings; they frequent coral reefs, crawling about or hanging on by the pectoral fins, which resemble arms with many-fingered hands. *Pterophryne histrio* inhabits floating masses of *Sargassum*, with which its coloration harmonizes.

The Chaunacidae comprise the two or three species of *Chaunax*, curious oceanic fishes somewhat broader than deep, red in colour, with the spinous dorsal represented only by the illicium, which is short, fleshy, transversely expanded, and placed on the upper surface of the snout. The Oncocephalidae or bat-fishes, of which some 40 species are known, have the illicium formed as in *Chaunax*, but it is contained in a cavity on the anterior surface of the snout, just above the mouth. The head and body are covered with bony tubercles or spines, and in most of the genera the tail is well marked off from a depressed circular or triangular disc. These are fishes of warm seas, living on the bottom, some in shallow water, but many at considerable depths. Principal genera: *Onchocephalus*, *Haliutea*, *Dibranchius*, *Malthopsis*.

Sub-order 3. **Ceratioidea**.—Distinguished by the absence of pelvic fins, by the reduced toothless lower pharyngeals, and by having the males dwarfed and parasitic on the females. These are oceanic fishes, inhabiting the middle depths, from about 500 to 2,000 metres below the surface; as there is little or no light in this region the majority are uniformly blackish in colour, and their bait, or terminal expansion of the illicium, is a luminous bulb. About 60 species are known, which have been grouped into ten well-defined families. From a consideration of the habits and conditions of life of these fishes, few in numbers as compared with the more active forms on which they prey, living a solitary life, floating about in the dark, it can be seen that a mature fish might have some difficulty in finding a mate. This difficulty appears to have been overcome by the males, as soon as they are hatched, when they are relatively numerous, seeking the females and if they find one holding on to her and remaining attached for life. Even so the males are rare, and have so far been discovered only on four females, belonging to three different families. The males must first attach themselves by the mouth, nipping a piece of the skin of the female and forming a papilla with which the lips fuse. In these fishes the lower elements of the hyoid and branchial arches support a freely movable "tongue,"

and this may either unite with the skin of the female inside the mouth (*Edriolychnus*) or may be pushed forwards between the branches of the lower jaw to form an attachment below and in front of the mouth (*Ceratias*, *Photocorynus*). By the former method the mouth is choked up, except for a tiny opening at the corner for the intake of water for respiration; by the latter the mouth is closed only in front, and by subsequent growth may be carried away from the female, to which the male is attached by upper and lower outgrowths from the head, which unite in front of the mouth and fuse with a projection from the skin of the female. Dissection shows that the union of male and female is complete; there is no boundary between them; they are connected by very vascular fibrous tissue, and the male appears to be nourished by the continuity of his blood system with that of the female, a unique type of parasitism. The male has a heart and gills, but is otherwise degenerate and quite incapable of feeding; he has no illicium, the mouth is closed and toothless, the gut is vestigial, and the testis nearly fills the abdominal cavity. Most of the ceratioids are piscivorous and have a large mouth, with slender acute depressible teeth in the jaws. In some, e.g., *Melanocetus*, *Linophryne*, the stomach is extraordinarily distensible, and they have been known to swallow fishes several times their own size. *Linophryne* is remarkable for its formidable teeth and for the possession of a barbel, which in some species is large and much branched. The illicium is articulated to the anterior end of a basal bone that lies in a trough on the upper surface of the skull; this bone may project, and in some species may be completely and permanently exerted as a long rod, which in *Ceratias* is nearly as long as the fish itself. *Lasiognathus* has such a rod, but in addition the line is produced beyond the bait to end in a triangle of hooks; this genus is also remarkable for the structure of the mouth; the slender premaxillaries project forwards and are connected with the head by a broad membrane, which forms the walls of a pouch when the upper jaw moves downwards; these fishes must enclose their prey whole; the bristle-like teeth cannot be used for piercing, but meet across and close the opening of the pouch in front of the lower jaw. In *Gigantactis* the illicium is inserted at the end of the snout, and in one species forms a fine line four times as long as the fish itself. *Himantolophus* is noteworthy for the complicated structure of the illicium, which bears several long tentacles. Two families of ceratioids, Neoceratiidae and Aceratiidae, contain little fishes that have lost the illicium and hunt their prey by smell and sight; in all of them the nasal sacs and nostrils are large. *Neoceratias* has the teeth represented by slender spines, hooked at the ends, movable and inserted in muscular pads, in two series in the lower jaw and in three above the mouth, two of which are placed on the upper surface of the snout. *Aceratias* is remarkable for its forwardly directed telescopic eyes.

Order 30. **Opisthomi**.—Elongate fishes allied to the Percomorphi. Body covered with small scales; dorsal and anal fins long, many-rayed, contiguous to or confluent with the small caudal; dorsal preceded by a series of isolated spines, except in *Chaudhuri*; pectorals well developed; pelvics absent. Mouth terminal, with villiform teeth. Posterior nostril in front of eye, anterior tubular, at the end of a fleshy tentacle at the end of snout. Gill-openings restricted from above, the operculum without free edge. Nasal bones very large, meeting in the middle line, and attached to the upper edge of the mesethmoid, which forms a vertical septum between the nasal sacs. Palatine a narrow lamina firmly attached to vomer, parasphenoid and lateral ethmoid; ectopterygoid articulating with lateral ethmoid external to palatine. No post-temporal; supra-cleithrum attached by ligament to third or fourth vertebra. Carnivorous fresh-water fishes of Africa and southern Asia; probably they burrow in the mud during the day and search for food at night; the peculiarities of the nostrils and olfactory organs indicate the importance of the sense of smell.

Order 31. **Symbranchii**.—Eel-shaped fishes, with the caudal fin very small, 8–10 rayed, and continuous with the dorsal and anal, which are rayless folds of the skin; no pectoral fins; pelvics, if present, jugular. No air-bladder. Gill-openings confluent below

but restricted from above, typically appearing as a transverse ventral slit. Skeleton much as in the Percomorphi, but entopterygoid absent, skull without basisphenoid, alisphenoid or opisthotic, sphenotic with a projection directed outwards and forwards. No ribs, epipleurals present.

Sub-order 1. *Alabetoidea*.—This group includes the single genus *Alabes*, little fishes of the coasts of Australia, known as "shore eels." Minute two-rayed pelvic fins are present, just behind the gill-opening, and the dorsal and anal fins are well-developed. The mouth is small, with a series of blunt compressed teeth in the jaws. The skull is broad and depressed, with the parasphenoid and frontals separated by an interspace and the parietals not meeting above the supraoccipital. The premaxillaries have strong posterior prodicals.

Sub-order 2. *Symbranchioidea*.—In the symbranchoid eels, pelvic fins are absent and the dorsal and anal are vestigial. The mouth is moderately large with acute teeth. The skull is elongate, with the parasphenoid united to each of the frontals by a long suture, and with the parietals meeting above the supraoccipital. The premaxillaries have no pedicels.

In the family Symbranchidae there are no respiratory sacs and the pectoral arch is attached to the skull by a forked post-temporal. *Macrotrema caligans* is a marine fish known from Penang and Singapore. The species of *Symbranchus* are found in fresh and brackish waters, rarely in the sea; one is known from Central and South America, one from west Africa, and one from India to New Guinea. *Monopterus* comprises a single species from the rivers of southern and eastern Asia. The Amphipnoidae include only *Amphipnoides cuchia* from the fresh and brackish waters of tropical Asia, which differs from the Symbranchidae especially in the development of a pair of air-breathing sacs, diverticula of the pharynx which lie on each side of the back-bone above the gills. These sacs push away the pectoral arch from the skull, and the post-temporal is absent; on the outside the sacs are covered by the opercular bones, which are enlarged and form thin, almost membranous laminae. The *cuchia* spends the greater part of its life out of the water, wriggling along the banks, in which it burrows during the dry season. It visits the water in search of food, worms, crustaceans and small molluscs.

Sub-class 3. **CROSSOPTERYGII**.—Scales, when ganoid, with a single superficial layer of ganoine above the cosmine layer, which has a very regular structure. Pectoral fins lobate, typically with all the radials articulating with the segmented metapterygium, and none directly with the pectoral arch; pelvic fins similar. Skull with few cartilage bones, generally differing from that of the Palaeopterygii in having the unpaired sphenoid postorbital. No branchiostegals, but often a pair of large gular plates. Clavicles present.

In the structure of the paired fins the fishes of this sub-class are more advanced than the Palaeopterygii. The scales may be regarded as derived from the palaeoniscoid scales by reduction of the ganoine and specialization of the cosmine. The ancestors of the Crossopterygii must have belonged to the Palaeopterygii, but some Rhipidistia retain primitive features unknown in any member of that group, notably the pineal foramen, and the complex structure of the lower jaw. The replacement of the branchiostegals by the extension backwards of the paired gulars found in many Palaeoniscidae has occurred in *Polypterus* also, and is doubtless related to the fact that these are sluggish fishes, breathing quietly; the paddle-like paired fins also indicate slow swimming.

Order 1. **Rhipidistia**.—Premaxillaries and maxillaries present; palato-quadrate not fused with skull; hyomandibular well-developed; pectoral fins obtusely or acutely lobate, articulating with pectoral arch by the proximal segment of the metapterygium. Devonian and Carboniferous fishes that have been arranged in three families, Osteolepidae, with simple teeth, ganoid scales, and obtusely lobate paired fins; Rhizodontidae, differing in the teeth with radially arranged folds of dentine and the cycloid scales; and Holoptychiidae, further differing in having acutely lobate pectoral fins. The Osteolepidae (*Osteolepis*, *Megalichthys*,

etc.) appear to be the ancestors of the four-footed vertebrates; the skull is very similar to that of the Stegocephalia (see AMPHIBIA) and the pectoral fin approaches closely the pentadactyle limb, the proximal segment of the metapterygium being the humerus, the next and the first radial the radius and ulna.

Order 2. **Actinistia**.—Highly specialized fishes apparently derived from the Rhipidistia (Stensio, 1921). Hyomandibular very small; palato-quadrates articulating with otic region of skull. Paired fins with short rounded lobes, the pectorals with a few radiating radials that may articulate direct with the pectoral arch. The Coelacanthidae range from the Carboniferous to the Cretaceous. Principal genera: *Coelacanthus*, *Undina*, *Macropoma*.

Order 3. **Dipneusti**.—Premaxillaries and maxillaries absent; palato-quadrates fused with skull; teeth forming a pair of plates on the palate, and one on the inside (prearticular) of each lower jaw. Paired fins acutely lobate, hyomandibular vestigial.

Of the Palaeozoic fishes of this order, the Devonian *Dipterus* resembles the Osteolepidae in having ganoid scales, two dorsal fins and a heterocercal caudal, but differs in having the top of the head covered with numerous small bones. Other genera more specialized in the structure of the scales and fins have the head roofed mainly by the large frontals and parietals.

In the living genera the bones of the cranial roof are few, with a large median bone, fronto-parietal—behind, and a smaller one—ethmoid—in front, and a pair of bones flanking the fronto-parietal in the otic regions; the scales are cycloid, and the vertical fins are continuous. The living Dipneusti belong to two families, Ceratodontidae and Lepidosirenidae. *Neoceratodus* of the rivers of Queensland is closely related to *Ceratodus*, which was widely distributed in Triassic and Jurassic times. The paired fins resemble paddles, and have an internal skeleton of a segmented axis with a series of radials on each side. The air-bladder is lung-like in structure. *Neoceratodus* is a large, sluggish fish, inhabiting stagnant pools. The eggs are laid singly, and the larva has neither external gills nor sucker. The Lepidosirenidae are much more specialized than the Ceratodontidae, and are more or less eel-like, with filamentous paired fins. The dental plates have three strong ridges, instead of the numerous radiating ridges found in other fishes of this order. There are two genera, *Protopterus* in Africa and *Lepidosiren* in South America; they breathe air like *Neoceratodus*, and in the dry season hibernate in deep burrows in the mud. Both make nests, that of *Protopterus* being a hole in the mud near the edge of a swamp, whereas that of *Lepidosiren* is a burrow at the bottom of the water. When the eggs are laid the male guards the nest. When hatched the larvae adhere to the mud by means of a glandular sucker behind the mouth; they are provided with four pairs of external gills. Later the sucker is lost, the gills degenerate, and the young fish leave the nest. In view of the fact that *Neoceratodus* has neither external gills nor sucker it seems probable that these structures in the Lepidosirenidae are not homologous with those of amphibian larvae, but are independently developed.

BIBLIOGRAPHY.—Bashford Dean has issued a bibliography of fishes in three volumes, 1916-23, published by the American Museum of Natural History; the Pisces section of the *Zoological Record*, published annually by the Zoological Society of London, should be consulted.

General Works. A. Gunther, *Introduction to the Study of Fishes* (1880); T. W. Bridge and G. A. Boulenger, *Cambridge Natural History, Fishes* (1904); D. S. Coloration of Fish.—The colours of the fishes of tropical reefs are as brilliant, and their colour patterns as bizarre, as those of any other group. Whatever proves, therefore, to be the chief function of their coloration is likely to be chief also in other vertebrate classes, insects and cephalopods, with whose system of pigmentation their own has much in common (see COLOURS OF ANIMALS). And since cryptic coloration is better known and more surely demonstrated than any other, it will be instructive to inquire how, generally, colour seems to serve for concealment among fishes. To obtain a satisfactory answer it is necessary to go down with them, and to view them as the diver sees them.

First, it must be noted that the surroundings in which the gaily coloured tropical reef-fishes live show colours as bright and varied as those of the fishes themselves. It was to demonstrate this fact objectively that the autochromes here reproduced were taken. A larger series would be necessary to show the range of the colour scale. Brown, olive and green, with many shades of grey, are the dominant bottom colours. There is much bright yellow, with buff and cream. Purple and red are not uncommon. The water itself provides another series, not to be forgotten; green, where it is shallow, clear and looked at from above; ultramarine, where it is

both deep and clear; blue or blue-grey, as the sky is blue, when one stands on the bottom and looks away through it toward the horizon, which is very near; blue-black or violet, as one looks down into it from some vantage-point on a vertical reef-front overhanging an unseen bottom far below. And finally there is the gleaming silver of the surface film, not a water colour, but an effect of reflection.

Colour that conceals for the most part repeats the background colour against which it is seen. Hence the question is asked: are the habits of the different species of fishes such that they are seen chiefly in surroundings and against backgrounds whose dominant colours are their own? This is not a problem which may be settled after superficial observation only. It calls for precise information concerning the horizontal range of the fishes, the natural colour, shade and texture of the bottom over which they swim, and the colour and cover lent to it by vegetation or sessile animals. It calls, too, for data regarding the illumination to which the fishes are exposed, bringing in the relation of their activity to the time of day. The vertical range of each in the normal round of its activities must also be narrowly investigated. This is not an unnecessarily refined analysis that is proposed. In roft. of water at Tortugas, Florida, there are four species of *Gnathypops* which live in burrows in a rocky or sandy bottom. Three spend most of their time, by day at least, in these shelters with only their heads protruding. The fourth species, when undisturbed, spends little time in its burrow, but floats and feeds at an angle of 45° at an average height of about 8 in. above it. This difference in habits brings it into very different relations with other animals from those in which the first three stand. Its food is not the same as theirs and, possibly as a direct result, its degree of infection by parasites is different also. Of a series of the three bottom-haunting forms examined, not one lacked a certain species of trematode encysted in its air-bladder. Some contained more than 50. Of the fourth species half were uninfected, and none contained more than five of the parasites. If, with such slight difference in the plane upon which some single major activity occurs, contact with other animal species may vary so greatly, it is evident that the key to the meaning of colour may be wholly overlooked, if the study of such differences is neglected. In this instance the difference in colour is instructive. The three species whose habits are most alike are all coloured with the mottled brown and grey of the bottom. The fourth is almost wholly bluish-grey. The case is not unique; blue-grey is a colour which is found on fishes that swim well off the bottom in the open water.

What holds good for blue holds good for other colours. Green is chiefly the colour of surface fishes of shallow water, or of fishes of green, weedy bottoms. Silver, in fishes of shallow water, seems to be confined to those which often or always swim just beneath the surface, and so with the others. Fishes whose habits confine them chiefly to one sort of habitat show in colour, and often in pattern, recognizable fitness for life in the places they occupy. They are commonly accepted examples of cryptic coloration, such as some of the flounders, and the sargassum fish, *Pterophryne gibba*. Others, whose habits lead them to range through a variety of surroundings or to feed at every level from the surface to the bottom, are marked, as *Abudefduf marginatus* is, with contrasting patterns of bands or blotches of colour dominant in different parts of their range. If they too may not be said to be cryptically coloured, it is only because the phrase has by use become limited in application. At surprisingly short distance some of their colours appear continuous with the whole or patches of background colour. Silhouettes are no longer visible. Obliteration is the function of colour and pattern in these fishes as surely as in the other examples mentioned. The conditions under which reduction of conspicuousness is to be achieved are different and call for the application of another formula. This may be a difficult conclusion to accept, but there is overwhelming evidence to support it.

It is readily demonstrable that countershading—the counter-gradation of pigment from darkest, on surfaces most exposed, to lightest on surfaces most hidden from light—is the basis of concealing coloration. Solid objects when uniformly coloured and

lighted from one side are shaded with tell-tale shadows on their faces turned away from the source of illumination. But countershaded solids fitly lighted show no such shadows revealing their rotundity. On the contrary, they seem flat silhouettes which background-matching patterns efface. But countershading is not a direct effect of exposure to light. It is part of an inherited mechanism whose function is concealment (W. H. Longley, *Jour. Exp. Zool.*, 1917). Its mere presence (and it is clearly present in most fishes), is presumptive evidence that their colours and patterns are cryptic in effect.

The patterns themselves, upon analysis, often permit of no other interpretation. Scores of species, for example, have longitudinal, vertical or oblique dark lines crossing the eye. Sometimes these lines are broad enough to include the whole orbit; usually, however, they are of the width of the pupil. Upon inspection those of the second sort can usually be resolved into seven parts, two without the orbit, two upon the sclerotic or the conjunctiva covering it, two upon the iris on opposite sides of the pupil, while the last is virtual—the retinal black seen through the pupil. It may be added that the sclerotic sectors extend peripherally under the orbital margins, so that the apparent continuity of the line persists even when the eye rolls. These patterns and very many others, some more, some less complex, mask the moving eye. Their function may be deduced from their relation.

Finally, there is the fact that the fishes are changeable in coloration, not rarely, but usually, in the case of bottom fishes or those which approach the bottom at all often, to feed or rest. In the great majority of species, these changes in colour and pattern, effected through a complex mechanism including the eye, nervous system and a series of chromatophores in the skin, are adaptive. By watching the fishes, or by leading them from place to place by offering them food, it may be shown clearly that in general the changes consist in putting off the colours dominant in those places from which the fishes have just come and in putting on the prevailing colours of those they have newly attained. When all is considered, there is little ground left for assuming that among fishes colour has any other really important function besides concealment. If there is another, it may be in connection with the act of breeding, for there are a good many fishes in which there is more or less display of changeable colour correlated with the exercise of the reproductive function. As a second exception may be mentioned sexually dimorphic coloration, which is fairly common. For functionless bright coloration, or for conspicuous coloration whose use lies in its conspicuousness, there is little place indeed. This is perhaps not to be wondered at. The hypothesis of immunity coloration, which would have it that bright colours in general are flaunted by creatures which are protected, by stings for example, or have a ready way of escape from their enemies, is founded in the case of fishes on superficial observation in the field and on misinterpretation of the results of uncontrolled experiments. The hypothesis of signal and recognition marks seems not to apply here, nor is there evidence to suggest the common occurrence of mimicry. (See also COLOURS OF ANIMALS.)

Nat.* (1917); G. H. Thayer, *Concealing Coloration in the Animal Kingdom* (1918); E. B. Poulton, *Animal Coloration*. (W. H. L.)

FISH-FLY, the name given, especially in North America, to small insects of the genus *Chauliodes* and allied genera, related to the alder-flies (*q.v.*). Fish-flies belong to the order Neuroptera (*q.v.*), sub-order Megaloptera. The larvae are aquatic.

FISHGUARD (*Abergwaun*), market town, urban district and packet station, north coast of Pembrokeshire, Wales, near the mouth of the river Gwaun. Pop. (1931) 2,963. The present town is perched high above a smaller harbour-village on an inlet on the south side of the bay. The importance of Fishguard is due to the local fisheries and the excellence of its harbour. Local interest centres around the attempted landing by General Tate, an Irish-American adventurer, with French soldiers in 1797. His force soon capitulated to the local militias. The G.W.R. company built at great expense a breakwater across the outer end of the

bay in the hope of using the harbour for ocean liners. A passenger and goods service with Rosslare on the opposite Irish coast has been maintained since 1906. Trans-atlantic liners called in 1908 to embark and disembark mails and passengers, but this soon ceased owing to difficulties of approach in rough or misty weather. Goodwick, in the parish of Llanwnda, situated near the breakwater, grew while the harbour was being built.

FISH-HAWK, a common name in America for the osprey (*q.v.*).

FISHING: see ANGLING.

FISHING-FROG: see ANGLER.

FISH-LOUSE, the name applied to small crustaceans of the order Copepoda (*q.v.*), external parasites of fishes, whales and other marine animals.

FISH MANURE: see FERTILIZERS.

FISK, JAMES (1834–1872), American financier, was born at Bennington (Vt.), on April 1, 1834. He was successively circus hand, hotel waiter, pedlar, and dry goods salesman. By his dealing in army contracts during the Civil War, he accumulated a considerable capital. In 1864 he became a stock-broker in New York and was employed by Daniel Drew as a buyer. He aided Drew in his war against Vanderbilt for the control of the Erie railway, and as a result of the compromise that was reached he and Jay Gould became members of the Erie directorate. Subsequently Fisk and Gould obtained control of the road. They carried financial "buccaneering" to extremes, their programme including open alliance with the Tweed "ring," the wholesale bribery of legislatures and the buying of judges. Their attempt to corner the gold market culminated in the fateful "Black Friday" of Sept. 24, 1869. Fisk was shot and killed in New York city by E. S. Stokes, a former business associate, on Jan. 6, 1872.

FISKE, JOHN (1842–1901), American historical, philosophical, and scientific writer, was born in Hartford (Conn.), March 30, 1842, and died at Gloucester (Mass.), July 4, 1901. Before entering college he had read widely in English literature, history, and ancient and modern languages. He graduated at Harvard in 1863, continuing to study languages and philosophy with zeal; he spent two years in the Harvard Law School and opened an office in Boston, but soon devoted the greater portion of his time to writing for periodicals. With the exception of one year, he resided at Cambridge (Mass.), from graduation until death. In 1869 he gave a course of lectures at Harvard on the Positive philosophy; next year he was history tutor. In 1871 he delivered 35 lectures on the doctrine of evolution, afterwards revised and expanded as *Outlines of Cosmic Philosophy* (1874); and between 1872 and 1879 he was assistant librarian. After that time he devoted himself to literary work and lecturing on history. Nearly all of his books were first given to the public in the form of lectures or magazine articles, revised and collected under a general title, such as *Myths and Myth-Makers* (1872), *Darwinism* (1879), *Excursions of an Evolutionist* (1883), *The Destiny of Man, Viewed in the Light of His Origin* (1884), *The Idea of God as affected by Modern Knowledge* (1885), and *A Century of Science* (1899).

He did much by the lucidity of his style to spread a knowledge of Darwin and Spencer in America, and through his strong faith vanquished prejudice and demonstrated that religion and evolution were not incompatible. His *Outlines of Cosmic Philosophy*, while setting forth the Spencerian system, made psychological and sociological additions of original matter, in some respects anticipating Spencer's later conclusions. Fiske's reputation was due to his historical writings; which were chiefly devoted to studies, in a unified general manner, of separate yet related episodes in American history.

They form a nearly complete colonial history, as follows: *The Discovery of America, with some Account of Ancient America, and the Spanish Conquest* (1892); *Old Virginia and her Neighbours* (1897); *The Beginnings of New England; or, The Puritan Theocracy in its Relations to Civil and Religious Liberty* (1889); *Dutch and Quaker Colonies in America* (1899); *The American Revolution* (1891); and *The Critical Period of American History, 1783–89* (1888). The minute investigations of more recent his-

torians are, however, somewhat supplanting these; the multiplicity of Fiske's interests prevented thorough mastery of any one field.

See J. S. Clark, *The Life and Letters of John Fiske* (1917) and "John Fiske, Evolutionist" in Lyman Abbott's *Silhouettes of My Contemporaries* (1921).

FISKE, MINNIE MADDERN (1865–), American actress, was born in New Orleans, the daughter of Thomas Davey. As a child she played, under her mother's name of Maddern, with several well-known actors. In 1882 she first appeared as a "star." In 1890 she married Harrison Grey Fiske and was absent from the stage for several years. In 1893 she reappeared in *Hester Crewe*, a play written by her husband, and afterwards acted a number of Ibsen's heroines, in Shakespearean rôles, and *Becky Sharp* in a dramatization of Thackeray's *Vanity Fair*. In 1901 she opened, in opposition to the American theatrical "trust," an independent theatre in New York, the Manhattan. She has won a considerable reputation in the United States as an emotional actress and as a comedienne, her "Mistress Page" in the 1927–28 revival of *The Merry Wives of Windsor* was particularly commended.

FISTULA, a term in surgery used to designate an abnormal communication leading either from the surface of the body to a normal cavity or canal, or from one normal cavity or canal to another. These communications are the result of disease or injury. They receive different names according to their situation: *lacrimal fistula* is the small opening left after the bursting of an abscess in the upper part of the tear-duct, near the root of the nose; *salivary fistula* is an opening into the salivary duct on the cheek; *anal fistula*, or *fistula in ano*, is a suppurating track near the outlet of the bowel; *urethral fistula* is the result of a giving way of the tissues behind a stricture. These are examples of the variety of the first kind of fistula; while *recto-vesical fistula*, a communication between the rectum and bladder, and *vesico-vaginal fistula*, a communication between the bladder and vagina, are examples of the second. The abnormal passage may be straight or tortuous, of considerable diameter or of narrow calibre. Fistulae may be caused by an obstruction of the normal channel, the result of disease or injury, which prevents, for example, the tears, saliva or urine, as the case may be, from escaping; their retention gives rise to inflammation and ulceration in order that an exit may be obtained by the formation of an abscess, which bursts, for example, into the gut or through the skin; the cavity does not close, and a fistula is the result. The fistulous channel remains open as long as the contents of the cavity or canal with which it is connected can pass through it. To obliterate the fistula one must remove the obstruction and encourage the flow along the natural channel; for example, one must open up the nasal duct so as to allow the tears to reach the nasal cavity, and the *lacrimal fistula* will close; and so also in the *salivary* and *urethral fistulae*. Sometimes it may be necessary to lay the channel freely open, to scrape out the unhealthy material which lines the track, and to encourage it to fill up from its deepest part, as in *anal fistula*; in other cases it may be necessary to pare the edges of the abnormal opening and stitch them together. (E. O.)

FIT. (1) A division of a poem, a canto, in this sense often spelled "fytte." (2) A sudden attack of illness, particularly one with convulsive paroxysms accompanied by unconsciousness, especially an attack of apoplexy or epilepsy.

FITCH, JOHN (1743–1798), American pioneer in steam-boat navigation, was born at Windsor, Conn., on Jan. 21, 1743. Largely self-educated, he became successively a clock-maker, brass-founder, silversmith and surveyor. During the Revolutionary War he was made a lieutenant and at Trenton and Valley Forge furnished supplies to the American troops. After the surrender of Cornwallis, he became deputy-surveyor for Kentucky. In 1782, when near Marietta, O., he was captured by the Indians, taken first to the British post at Detroit, thence to Montreal and there later released. He returned to eastern Pennsylvania where early in 1785 he first conceived the idea of utilizing the power of steam in navigation. He built a model steamboat, with a small engine made of brass and wooden paddle wheels,

which he tested on a mill pond near Davisville, Pennsylvania. To gain funds with which to build a commercial steamboat, he published in 1785 his "Map of the Northwest." In 1786 he constructed a boat propelled by steam, which was operated on the Delaware river at Philadelphia. In the same year New Jersey enacted a law giving Fitch exclusive rights for boats propelled by steam; in 1787 Pennsylvania, Delaware, New York and Virginia passed similar laws. Fitch applied to the legislatures of several States for pecuniary aid in developing his invention, but without result. He succeeded, however, in building a larger steamboat in 1787, and in 1790 he operated between Philadelphia and Trenton a steamboat, making regularly advertised trips and carrying both freight and passengers.

But these undertakings, proving financially unsuccessful, were abandoned, and Fitch failed also in his attempt in 1793 to introduce steam navigation into France. While in the operation of his various steamboats Fitch made use of steam-propelled oars, paddle wheels and a primitive type of screw, he was unable to convince the public of the practical value of steam navigation. In 1796 he went again to Kentucky, where he found his lands overrun by squatters. Reaping from his inventions nothing but disappointment and poverty, his health gave way and he died at Bardstown, Ky. on July 2, 1798. According to Westcott, his first biographer, he took his own life, but this is now disputed. In 1927 a national monument, provided by Congress in recognition of his inventions, was erected in Bardstown.

See Thompson Westcott, *The Life of John Fitch*, based on Fitch's autobiographical records (Phila. 1857, ed. 2, 1878); R. C. Fitch, *History of the Fitch Family* (1929).

FITCH, SIR JOSHUA GIRLING (1824-1903), English educationist, second son of Thomas Fitch, of a Colchester family, was born in Southwark, London, in 1824. He entered the education inspectorate in 1863, and from 1885 to 1894 was chief inspector of training colleges. Fitch was a strong advocate of the higher education of women, and he was constantly looked to for counsel and direction on educational subjects. In 1896 he was knighted. He published an authoritative criticism of *Thomas and Matthew Arnold, and Their Influence on English Education* (1901). He died on July 14, 1903, in London.

See A. L. Lilley, *Sir Joshua Fitch* (1906).

FITCH, RALPH (fl. 1583-1606), London merchant, one of the earliest English travellers and traders in Mesopotamia, the Persian Gulf and Indian Ocean, India proper, and Indo-China. In Jan. 1583 he embarked on the "Tiger" for Tripoli and Aleppo in Syria (see Shakespeare, *Macbeth*, Act i. sc. 3), together with J. Newberie, J. Eldred and two other merchants of the Levant Company. From Aleppo he reached the Euphrates, descended the river to Fallujah, crossed southern Mesopotamia to Baghdad, and dropped down the Tigris to Basra (May to July 1583). Here Eldred stayed behind to trade, while Fitch and the rest sailed down the Persian gulf to Ormuz, where they were arrested as spies and sent prisoners to the Portuguese viceroy at Goa (September to October). Through the sureties procured by two Jesuits (one being Thomas Stevens, formerly of New college, Oxford, the first Englishman known to have reached India by the Cape route, in 1579) Fitch and his friends regained their liberty, and escaping from Goa (April 1584) travelled through the heart of India to the court of the great Mogul Akbar, then probably at Agra. In Sept. 1595 Newberie left on his return journey overland *viâ* Lahore (he disappeared in the Punjab), while Fitch descended the Jumna and the Ganges, visiting Benares, Patna, Kuch, Behar, Hugli, Chittagong, etc. (1585-86), and pushed on by sea to Pegu and Burma. Here he visited the Rangoon region, ascended the Irawadi some distance, acquired a remarkable acquaintance with inland Pegu, and even penetrated to the Siamese Shan States (1586-87). Early in 1588 he visited Malacca; in the autumn of this year he began his homeward travels, first to Bengal; then round the Indian coast, touching at Cochin and Goa, to Ormuz; next up the Persian gulf to Basra and up the Tigris to Mosul (Nineveh); finally *viâ* Urfa, Bir on the Euphrates, Aleppo and Tripoli, to the Mediterranean. He reappeared in London on April 29, 1591. His experience was greatly valued by the founders of the East India Com-

pany, who specially consulted him on Indian affairs. He died c. Oct. 5, 1611.

See Hakluyt, *Principal Navigations* vol. ii., part i., pp. 245-271, esp. 250-268 (1599); Linschoten, *Voyages (Itineraris)*, part i. ch. xcii. vol. ii. pp. 158-169, etc. (Hakluyt Soc. ed.); Stevens and Birdwood, *Court Records of the East India Company 1599-1603*, esp. pp. 26, 123 (1886); *State Papers, East Indies, etc.*, 1513-1610, No. 36 (1862); Pinkerton, *Voyages and Travels*, ix. 406-425 (1808-1814). J. Horton Ryley, *Ralph Fitch, England's Pioneer to the Indies* (1899).

FITCH, WILLIAM CLYDE (1865-1909), American playwright, was born on May 2, 1865, in Elmira, N.Y., and graduated from Amherst college in 1886. An interest in literature, already formed, led him to establish himself in New York city, where he began writing short stories for various magazines. His best known play, *Beau Brummel*, produced by Richard Mansfield in 1890, was almost his first, and it at once brought him recognition. He was a prolific writer and between 1890 and his death produced 36 original plays and 24 adaptations. Among his most important, besides *Beau Brummel*, were *The Climbers* (1901), *The Girl with the Green Eyes* (1902), *The Truth* (1907) and *The City* (1909). *Captain Jinks of the Horse Marines* (1902) was a charming light comedy which gave Ethel Barrymore one of her first opportunities. Fitch's plays show humour and facility in dialogue and expert knowledge of theatre technique, but lack strength and universality. He died in France on Sept. 4, 1909.

See M. J. Moses and V. Gerson, editors, *Plays by Clyde Fitch* (1915) and *Clyde Fitch and His Letters* (1924); also A. H. Quinn, *History of the American Drama* (1927).

FITCHBURG, a city of Massachusetts, U.S.A., 48m. W.N.W. of Boston, on the north branch of the Nashua river; one of the county seats of Worcester county. It is served by the Boston and Maine and the New York, New Haven and Hartford railways. The population was 41,029 in 1920 (32% foreign-born white) and was 40,692 in 1930 by the Federal census. The city has an area of 28.4 sq.m., varying from 430 to 550ft. in altitude, and including much picturesque scenery. It is the seat of a State normal school (established 1895). Fitchburg has been an important industrial centre for more than a century, and has over 100 manufacturing establishments, many of them large and of national reputation. The factory output in 1927 was valued at \$46,710,242. Paper is the leading product (400 tons daily), and is followed by foundry and machine products, woollen and worsted goods and a great variety of articles produced in smaller quantities. The assessed valuation of property in 1926 was \$62,572,050. Fitchburg was incorporated as a town in 1764, and was named after John Fitch, a citizen who did much to secure incorporation. It was chartered as a city in 1872.

FITCHEW, a name applied to the ferret and also to the polecat (*qq.v.*). Earlier forms of the word are *ficheux*, *fecheu* and *fitcholl*.

FITTER. A toolfitter makes or fits up press tools, dies, cutting tools for automatic machines, and parts of such machines closely related to the operation of the tools. A pipe-fitter attends to the cutting, bending, screwing, fitting in place and joint-making of iron, steel, copper or brass pipes in various engines and machines, and installations as in factories, power stations and on board ship. An assembler is in effect a fitter of no manual skill save that of quickness, for all the parts are machined accurately to gauges (see *ASSEMBLE*) and few tools are employed.

FITTIG, RUDOLF (1835-1910), German chemist, was born at Hamburg on Dec. 6, 1835. He studied chemistry at Göttingen, graduating as Ph.D. with a thesis on acetone in 1858. He subsequently held several appointments at Göttingen, being *Privat-docent* (1860), and extraordinary professor (1870); in 1870 he obtained the chair at Tübingen, and in 1876 that at Strasbourg. Fittig's researches were entirely in organic chemistry, and covered a wide field. He observed that aldehydes and ketones may be reduced to secondary and tertiary glycols, which he named pinacones, and also that certain pinacones when distilled with dilute sulphuric acid gave pinacolines. The unsaturated acids also received much attention, and he discovered the internal anhydrides of oxyacids, termed lactones. In 1863 he introduced the reaction known by his name. In 1855 A. Wurtz had shown that

when sodium acted upon alkyl iodides, the alkyl residues combined to form more complex hydrocarbons; Fittig showed that a mixture of an aromatic and an alkyl halide, under similar treatment, yielded homologues of benzene. He investigated Perkin's reaction and shed some light on its mechanism. These researches incidentally solved the constitution of coumarin, the odoriferous principle of woodruff. Fittig and Erdmann's observation that phenyl isocrotonic acid readily yielded α -naphthol by loss of water was of much importance, since it afforded valuable evidence as to the constitution of naphthalene. They also investigated certain hydrocarbons found in coal tar distillates and solved the constitution of phenanthrene. We also owe much of our knowledge of the alkaloid piperine to Fittig, who in collaboration with Ira Remsen established its constitution in 1871. Fittig edited several editions of Wohler's *Grundriss der organischen Chemie* (11th ed., 1887) and wrote an *Unorganische Chemie* (3rd, 1882). His researches have been recognized by many scientific societies and institutions, the Royal Society awarding him the Davy medal in 1906. He died at Strasbourg on Nov. 19, 1910.

FITTING, HANS (1877—), German botanist, was born on April 23, 1877, at Halle. In 1907 he became professor at Strasbourg, in 1910 at Halle, in 1911 director of the botanical institute at Hamburg, and in 1912 at Bonn. Since his journeys in 1907 through lower India, Ceylon and Egypt, and in 1910 through the Sahara, Fitting has devoted himself to work on orchids, the rubber plant, the sensitiveness of mimosa, osmotic pressure in desert plants and the metabolism of salts in the cell. He has published numerous papers in *Jahrbücher für wissenschaft. Botanik*, which he has edited since 1920.

FITTON, MARY (c. 1578–1647), identified by some writers with the "dark lady" of Shakespeare's sonnets, was the daughter of Sir Edward Fitton of Gawsorth, Cheshire, and was baptized on June 24, 1578. About 1595 Mary Fitton became maid of honour to Queen Elizabeth. Her father recommended her to the care of Sir William Knollys, comptroller of the queen's household, who was 50 and already married, but he soon became suitor to Mary Fitton, in hope of the speedy death of the actual Lady Knollys. There is no hint in her authenticated biography that she was acquainted with Shakespeare. William Kemp, who was a clown in Shakespeare's company, dedicated his *Nine Daies Wonder* to Mistress Anne (perhaps an error for Mary) Fitton, "Maid of Honour to Elizabeth"; and there is a sonnet addressed to her in an anonymous volume, *A Woman's Woorth defended against all the Men in the World* (1599). In 1600 Mary Fitton led a dance in court festivities at which William Herbert, later earl of Pembroke, is known to have been present; and shortly afterwards she became his mistress. In Feb. 1601 Pembroke was sent to the Fleet in connection with this affair, but Mary Fitton, whose child died soon after its birth, appears simply to have been dismissed from court. Mary Fitton seems to have gone to her sister, Lady Newdigate, at Arbury. A further scandal has been fixed on Mary Fitton by George Ormerod, author of *History of Cheshire*, in a ms. quoted by T. Tyler (*Academy*, Sept. 27, 1884). She married Captain Polwhele, by whom she had a son and daughter. Polwhele died in 1609 or 1610, about three years after his marriage. Her second husband, Logher, died in 1636. Her own will, which was proved in 1647, gives her name as "Mary Lougher." In Gawsorth church there is a painted monument of the Fittons, in which Anne and Mary are represented kneeling behind their mother. It is stated that from what remains of the colouring Mary was a dark woman, which is of course essential to her identification with the lady of the sonnets, but in the portraits of Arbury (the identity of which has been challenged), described by Lady Newdigate-Newdegate in her *Gossip from a Muniment Room* (1897) she has brown hair and grey eyes. (See also SHAKESPEARE, WILLIAM.)

FITTON, WILLIAM HENRY (1780–1861), British geologist, was born in Dublin in Jan. 1780. Educated at Trinity college, in that city, and at Edinburgh university, he took a medical practice at Northampton in 1812, and for some years the duties of his profession engrossed his time. In 1820 he settled in London and devoted himself to the science of geology. His "Observations on some of the Strata between the Chalk and the

Oxford Oolite, in the South-east of England" (*Trans. Geol. Soc.* ser. 2, vol. iv.) embodied a series of researches extending from 1824 to 1836, and form the classic memoir familiarly known as Fitton's "Strata below the Chalk." In this great work he established the true succession and relations of the Upper and Lower Greensand, and of the Wealden and Purbeck formations, and elaborated their detailed structure. He had been elected F.R.S. in 1815, was president of the Geological Society of London 1827–29, and was awarded the Wollaston medal by the Geological Society in 1852. He died in London on May 13, 1861.

See the obituary notice by R. I. Murchison in *Quart. Journ. Geol. Soc.* vol. xviii., 1862, p. xxx.

FITZBALL, EDWARD (1792–1873), English dramatist, was born at Burwell, Cambridgeshire, the son of a farmer. He produced some dramatic pieces at Norwich theatre, and the marked success of his *Innkeeper of Abbeville* (1820), together with the acceptance of one of his pieces at the Surrey theatre by Thomas Dibdin, induced him to settle in London. During the next 25 years he produced a great number of plays, most of which were highly successful. He had a special talent for nautical drama. His *Floating Beacon* (Surrey theatre, April 19, 1824) ran for 140 nights, and his *Pilot* (Adelphi, 1825) for 200 nights. His greatest triumph in melodrama was perhaps *Jonathan Bradford, or the Murder at the Roadside Inn* (Surrey theatre, June 12, 1833). He died at Chatham on Oct. 27, 1873.

His autobiography, *Thirty-Five Years of a Dramatic Author's Life* (2 vols., 1859), is a naïve record of his career. Numbers of his plays are printed in *Cumberland's Minor British Theatre*.

FITZGERALD, the name of an historic Irish house, which descends from Walter, son of Other, who at the time of the Domesday Survey (1086) was castellan of Windsor and a tenant-in-chief in five counties. From his eldest son William, known as "de Windsor," descended the Windsors of Stanwell, of whom Andrew Windsor was created Lord Windsor of Stanwell (a Domesday possession of the house) by Henry VIII., which barony is now vested in the earl of Plymouth, his descendant in the female line. Of Walter's younger sons, Robert was given by Henry I. the barony of Little Easton, Essex; Maurice obtained the stewardship (*dapiferatus*) of the great Suffolk abbey of Bury St. Edmunds; Reinald the stewardship to Henry I's queen, Adeliza; and Gerald (also a *dapifer*) became the ancestor of the Fitz Gerald. As constable and captain of the castle that Arnulf de Montgomery raised at Pembroke, Gerald strengthened his position in Wales by marrying Nesta, sister of Griffith, prince of South Wales, who bore to him famous children, "by whom the southern coast of Wales was saved for the English and the bulwarks of Ireland stormed." Of these sons William, the eldest, was succeeded by his son Odo, who was known as "de Carew," from the fortress of that name at the neck of the Pembroke peninsula, the eldest son Gerald having been slain by the Welsh. The descendants of Odo held Carew and the manor of Moulsoford, Berks, and some of them acquired lands in Ireland. But the wild claims of Sir Peter Carew, under Queen Elizabeth, to vast Irish estates, including half of "the kingdom of Cork," were based on a fictitious pedigree. Odo de Carew's brothers, Reimund "Fitz William" (known as "Le Gros") and Griffin "Fitz William," took an active part in the conquest of Ireland.

Returning to Gerald and Nesta, their son David "Fitz Gerald" became bishop of St. David's (1147–1176), and their daughter Angharat mother of Gerald de Barri (Giraldus Cambrensis, *q.v.*). A third son, Maurice, obtained from his brother the stewardship (*dapiferatus*) of St. David's, c. 1174, and having landed in Ireland in 1169, on the invitation of King Dermot, founded the fortunes of his house there, receiving lands at Wexford, where he died and was buried in 1176. His eventual territory, however, was the great barony of the Naas in Ophaley (now in Kildare), which Strongbow granted him with Wicklow Castle; but his sons were forced to give up the latter. His eldest son William succeeded him as baron of the Naas and steward of St. David's, but William's granddaughter carried the Naas to the Butlers and so to the Loundresses. Gerald, a younger son of Maurice, who obtained lands in Ophaley, was father of Maurice "Fitz Gerald," who was

justiciar of Ireland from 1232 to 1245. In 1234 he fought and defeated his overlord, the earl marshal, Richard, earl of Pembroke, and he also fought for his king against the Irish, the Welsh and in Gascony, dying in 1257. He held Maynooth Castle, the seat of his descendants.

Earls of Kildare.—The justiciar left a grandson Maurice (son of his eldest son Gerald) and a younger son Maurice, of whom the latter was justiciar for a year in 1272, while the former, as heir male and head of the race, inherited the Ophaley lands, which he is said to have bequeathed at his death (1287) to John "Fitz Thomas," whose fighting life was crowned by a grant of the castle and town of Kildare, and of the earldom of Kildare to him and the heirs male of his body (May 14, 1316). Dying shortly after, he was succeeded by his son Thomas, son-in-law of Richard (de Burgh) the "red earl" of Ulster, who received the hereditary shrievalty of Kildare in 1317, and was twice (1320, 1327) justiciar of Ireland for a year. His younger son Maurice "Fitz Thomas," 4th earl (1331–1390), was frequently appointed justiciar, and was great-grandfather of Thomas, the 7th earl (1427–1477), who between 1455 and 1475 was repeatedly in charge of the government of Ireland as "deputy," and who founded the "brotherhood of St. George" for the defence of the English Pale. He was also made lord chancellor of Ireland in 1463. His son, Gerald, the 8th earl (1477–1513), called "More" (the Great), was deputy governor of Ireland from 1481 for most of the rest of his life, though imprisoned in the Tower two years (1494–96) on suspicion as a Yorkist. He was mortally wounded while fighting the Irish as "deputy." Gerald, the 9th earl (1513–1534), followed in his father's steps as deputy, fighting the Irish, till the enmity of the earl of Ormonde, the hereditary rival of his house, brought about his deposition in 1520. In spite of temporary restorations he finally died a prisoner in the Tower.

In his anger at his rival's successes the 9th earl had been led, it was suspected, into treason, and while he was a prisoner in England his son Lord Thomas Fitzgerald (*q.v.*), "Silken Thomas," broke out into open revolt (1534), and declared war on the Government; his followers slew the archbishop of Dublin and laid siege to Dublin Castle. He and his five uncles were hanged as traitors in Feb. 1537, and acts of attainder completed the ruin of the family.

But the earl's half-brother, Gerald (whose sister Elizabeth was the earl of Surrey's "fair Geraldine"), a mere boy, had been carried off, and, after many adventures at home and abroad, returned to England after Henry VIII.'s death, and to propitiate the Irish was restored to his estates by Edward VI. (1552). Having served Mary in Wyatt's rebellion, he was created by her earl of Kildare and Lord Offaley, on May 13, 1554, but the old earldom (though the contrary is alleged) remained under attainder. Although he conformed to the Protestant religion under Elizabeth and served against the Munster rebels and their Spanish allies, he was imprisoned in the Tower on suspicion of treason in 1583. But the acts attainting his family had been repealed in 1569, and the old earldom was thus regained. In 1585 he was succeeded by his son Henry ("of the Battleaxes"), who was mortally wounded when fighting the Tyrone rebels in 1597. On the death of his brother in 1599 the earldom passed to their cousin Gerald, whose claim to the estates was opposed by Lettice, Lady Digby, the heir-general. She obtained the ancestral castle of Geashill with its territory and was recognized in 1620 as Lady Offaley for life. George, the 16th earl (1620–1660), had his castle of Maynooth pillaged by the Roman Catholics in 1642, and after its subsequent occupation by them in 1646 it was finally abandoned by the family.

The history of the earls of Kildare after the Restoration was uneventful save for the re-acquisition in 1739 of Carton, which thenceforth became the seat of the family, until James, the 20th earl (1722–1773), who obtained a viscounty of Great Britain in 1747, built Leinster House in Dublin, and formed a powerful party in the Irish parliament. In 1756 he was made lord deputy; in 1760 he raised the Royal Irish Regiment of Artillery; and in 1766 he received the dukedom of Leinster, which remained the only Irish dukedom till that of Abercorn was created in 1868.

His wealth and connections secured him a commanding position. Of his younger children, one son was created Lord Lecale; another was the well known rebel, Lord Edward Fitzgerald; another was the ancestor of Lord De Ros; and a daughter was created Baroness Rayleigh. William Robert, the 2nd duke (1749–1804), was a cordial supporter of the Union, and received nearly £30,000 for the loss of his borough influence. In 1883 the family was still holding over 70,000 acres in Co. Kildare; but, after a tenure of nearly 750 years, arrangements were made to sell them to the tenants under the recent Land Purchase Acts. In 1893 Maurice Fitzgerald (b. 1887) succeeded his father Gerald, the 5th duke (1851–1893), as 6th duke of Leinster.

Earls of Desmond.—The other great Fitzgerald line was that of the earls of Desmond, who were undoubtedly of the same stock and claimed descent from Maurice, the founder of the family in Ireland, through a younger son Thomas. Thomas "Fitz Maurice" *Nappagh* ("of the ape"), justice of Ireland in 1295, obtained a grant of the territory of "Decies and Desmond" in 1292. His son Maurice Fitz Thomas or Fitzgerald (d. 1356), inheriting vast estates in Munster, and strengthening his position by marrying a daughter of Richard de Burgh, earl of Ulster, was created earl of Desmond (*i.e.*, south Munster) on Aug. 22, 1329, and Kerry was made a palatine liberty for him. The greatest Irish noble of his day, he led the Anglo-Irish party against the English. He surrendered in England to the king and was imprisoned, but eventually regained favour, and was even made viceroy himself in 1355. Two of his sons succeeded in turn, Gerald, the 3rd earl (1359–98), being appointed justiciar (*i.e.*, viceroy) in 1367, despite his adopting his father's policy which the Crown still wished to thwart. But he was superseded two years later, and defeated and captured by the native king of Thomond shortly after. Yet his sympathies were distinctly Irish. The remote position of Desmond in the south-west of Ireland tended to make the succession irregular on native lines, and a younger son succeeded as 6th or 7th earl about 1422. His son Thomas, the next earl (1462–67), governed Ireland as deputy from 1463 to 1467, and upheld the endangered English rule by stubborn conflict with the Irish. Yet Tiptoft, who superseded him, procured his attainder with that of the earl of Kildare, on the charge of alliance with the Irish, and he was beheaded on Feb. 14, 1468, his followers in Munster avenging his death by invading the Pale. His younger son Maurice, earl from 1487 to 1520, was one of Perkin Warbeck's Irish supporters, and besieged Waterford on his behalf. His son James (1520–29) was proclaimed a rebel and traitor for conspiring with the French king and with the emperor. At his death the succession reverted to his uncle Thomas (1529–34), then an old man, at whose death there was a contest between his younger brother Sir John "of Desmond" and his grandson James, a court page of Henry VIII. Old Sir John secured possession till his death (1536), when his son James succeeded *de facto*, and *de jure* on the rightful earl being murdered by the usurper's younger brother in 1540. Intermarriage with Irish chieftains had by this time classed the earls among them, but although this James looked to their support before 1540, he thenceforth played so prudent a part that in spite of the efforts of the Butlers, the hereditary foes of his race, he escaped the fate of the Kildare branch and kept Munster quiet and in order for the English till his death in 1558. His four marriages produced a disputed succession and a break-up of the family. His eldest son Thomas "Roe" (the Red) was disinherited, and failed to obtain the earldom, which was confirmed by Elizabeth to his half-brother Gerald "the rebel earl" (1558–1583) (*see* DESMOND, GERALD FITZGERALD, 15TH EARL OF).

But the influence of the Fitzgeralds remained powerful even after the forfeiture of their estates after the execution of the 15th earl. The disinherited Thomas "Roe" left a son, James "Fitz Thomas," who, succeeding him in 1595 and finding that the territory of the earls would never be restored, assumed the earldom and joined O'Neill's rebellion in 1598, at the head of 8,000 of his men. He was eventually seized (1601) by his kinsman the White Knight, Edmund Fitz Gibbon, whose sister-in-law he had married, and sent to the Tower. The "sugan" (sham) earl lingered there obscurely as "James M'Thomas" till his death. In consequence of

his rebellion and the devotion of the Irish to his race, James, son of Gerald, "the rebel earl," who had remained in the Tower since his father's death (1583), was restored as earl of Desmond and sent over to Munster in 1600, but he, known as "the queen's earl," could, as a Protestant, do nothing, and he died unmarried in 1601. The "sugan" earl's brother John, who had joined in his rebellion, escaped into Spain, and left a son Gerald, who appears to have assumed the title and was known as the Conde de Desmond. He was killed in the service of the emperor Ferdinand in 1632.

The Fitzmaurices.—There can be no doubt that the house of Fitzmaurice was also of this stock, although their actual origin, in the 12th century, is doubtful. From a very early date they were feudal lords of Kerry, and their dignity was recognized as a peerage by Henry VII. in 1489. The isolated position of their territory ("Clanmaurice") threw them even more among the Irish than the earls of Desmond, and they often adopted the native form of their name, "MacMorris." Under Elizabeth the lords of Kerry narrowly escaped sharing the ruin of the earls. The conduct of Thomas in the rebellion of James "Fitz Maurice" was suspicious, and his sons joined in that of the earl of Desmond, while he himself was a rebel in 1582. Patrick, his successor (1590–1600), was captured in rebellion (1587), and when free, joined the revolt of 1598, as did his son and heir Thomas, who continued in the field till he obtained pardon and restoration in 1603, though suspect till his death in 1630. His grandson withdrew to France with James II., but the next peer became a supporter of the Whig cause, married the eventual heiress of Sir William Petty, and was created earl of Kerry in 1723. From him descended the family of Petty-Fitzmaurice, who obtained the marquessate of Lansdowne (q.v.) in 1818, and still hold among their titles the feudal barony of Kerry together with vast estates in that county.

From the three sons by a second wife of one of the earls of Desmond's ancestors, descended the hereditary White Knights, Knights of Glin and Knights of Kerry, these feudal dignities having, it is said, been bestowed upon them by their father, as Lord of Decies and Desmond. Glin Castle, Co. Limerick, is still the seat of the (Fitzgerald) Knight of Glin. Valencia Island is now the seat of the Knights of Kerry, who received a baronetcy in 1880.

Hist. Rev.*, xviii.

FITZGERALD, LORD EDWARD (1763–1798), Irish patriot, fifth son of James, 1st duke of Leinster, by his wife Emilia Mary, daughter of Charles Lennox, 2nd duke of Richmond, was born at Carton House, near Dublin, on Oct. 15, 1763. Joining the army in 1779, Fitzgerald served in America on the staff of Lord Rawdon (afterwards marquess of Hastings); at the battle of Eutaw Springs (Sept. 8, 1781) he was severely wounded. In 1783 Fitzgerald returned to Ireland and became member for Athy in the Irish parliament. He acted with the small Opposition group led by Grattan (q.v.), but took no prominent part in debate. After completing his military education at Woolwich he made a tour through Spain in 1787; and then, dejected by unrequited love for his cousin Georgina Lennox (afterwards Lady Bathurst), he sailed for New Brunswick to join the 54th Regiment with the rank of major. In Feb. 1789, guided by compass, he traversed the country, practically unknown to white men, from Frederickstown to Quebec, falling in with Indians by the way, with whom he fraternized; and in a subsequent expedition he was formally adopted at Detroit by the Bear tribe of Hurons as one of their chiefs, and made his way down the Mississippi to New Orleans, whence he returned to England.

Fitzgerald, who had meanwhile been elected to the Irish parliament for Kildare, refused the command of an expedition against Cadiz offered him by Pitt, and devoted himself for the next few years to society and his parliamentary duties. He was intimate with his relative C. J. Fox, with R. B. Sheridan and other leading

Whigs. According to Thomas Moore, Fitzgerald was the only one of the numerous suitors of Sheridan's first wife whose attentions were received with favour. He visited Paris in Oct. 1792. He lodged with Thomas Paine, and listened to the debates in the Convention. On Nov. 18 he supported a toast at a banquet to "the speedy abolition of all hereditary titles and feudal distinctions," and repudiated his own title—an act for which he was dismissed from the army. Fitzgerald now became enamoured of a young girl named Pamela, a *protégée* of Mme. de Genlis (q.v.). It was commonly believed that she was the daughter of Madame de Genlis herself by Philippe (Égalité), duke of Orleans. On Dec. 27, 1792 Fitzgerald and Pamela were married at Tournay, one of the witnesses being Louis Philippe, afterwards king of the French, and in Jan. 1793 the couple reached Dublin.

Discontent in Ireland was now finding a focus in the Society of the United Irishmen, and in the Catholic Committee, an organization formed a few years previously, chiefly under the direction of Lord Kenmare. Fitzgerald, fresh from the gallery of the Convention in Paris, returned to his seat in the Irish parliament, and threw himself actively into the work of opposition. Within a week of his arrival he was ordered into custody and required to apologize at the bar of the House for violent denunciations of a government proclamation. In 1796 he joined the United Irishmen, whose aim was now avowedly the establishment of an independent Irish republic. In May 1796 Wolfe Tone was in Paris endeavouring to obtain French assistance for an insurrection in Ireland. In the same month Fitzgerald and his friend Arthur O'Connor proceeded to Hamburg, where they opened negotiations with the Directory through Reinhard, French minister to the Hanseatic towns. The duke of York, meeting Pamela at Devonshire House on her way through London with her husband, had told her that "all was known" about his plans, and advised her to persuade him not to go abroad. The proceedings of the conspirators at Hamburg were revealed by an informer, Samuel Turner. The result of the Hamburg negotiations was Hoche's abortive expedition to Bantry Bay in December 1796. In Sept. 1797 the informer MacNally betrayed Fitzgerald's share in directing the conspiracy of the United Irishmen. He was head of the military committee; he had papers showing that 280,000 men were ready to rise, and the leaders were hoping for a French invasion to make good the deficiency in arms and to give support to a popular uprising. But French help proving dilatory and uncertain, Fitzgerald advocated action without waiting for foreign aid. On March 12, 1798 information given by Thomas Reynolds led to the seizure of a number of conspirators at the house of Oliver Bond. Fitzgerald, warned by Reynolds, was not among them and the opportunity of leaving Ireland was open to him. But he refused to desert others who could not escape, and whom he had himself led into danger. On March 30 a proclamation establishing martial law and authorizing the military to act without orders from the civil magistrate, which was acted upon with revolting cruelty in several parts of the country, precipitated the crisis.

On May 11 a reward of £1,000 was offered for Fitzgerald's apprehension. May 23 was the date fixed for the general rising. Since the arrest at Bond's, Fitzgerald had been in hiding, latterly at the house of one Murphy, a feather dealer, in Thomas Street, Dublin. The secret of his hiding place was disclosed by a Catholic barrister named Magan, to whom the stipulated reward was ultimately paid through Francis Higgins, another informer. On May 19 Fitzgerald was arrested after a desperate struggle in which he mortally wounded one of his captors, and was himself disabled by a pistol shot. He was taken to Newgate gaol, and there died of his wound on June 4, 1798. An Act of Attainder (repealed in 1819) was passed, confiscating his property, and his wife was compelled to leave the country before her husband died.

Pamela, who was scarcely less celebrated than Fitzgerald himself, went to Hamburg, where in 1800 she married J. Pitcairn, the American consul. She remained to the last passionately devoted to the memory of her first husband; and she died in Paris in Nov. 1831. A portrait of Pamela is in the Louvre. She had three children by Fitzgerald: Edward Fox (1794–1863); Pamela, after-

wards wife of General Sir Guy Campbell; and Lucy Louisa, who married Captain Lyon, R.N.

Lord Edward Fitzgerald was of small stature and handsome features. He had a winning personality, and a warm, affectionate and generous nature, which made him greatly beloved by his family and friends; he was humorous, light-hearted, sympathetic, adventurous. But he was entirely without the weightier qualities requisite for such a part as he undertook to play in public affairs. Reinhard, who considered Arthur O'Connor "a far abler man," accurately read the character of Lord Edward Fitzgerald as that of a young man "incapable of falsehood or perfidy, frank, energetic, and likely to be a useful and devoted instrument; but with no experience or extraordinary talent, and entirely unfit to be chief of a great party or leader in a difficult enterprise."

See Thomas Moore, *Life and Death of Lord Edward Fitzgerald* (2 vols., 1832), also a revised edition entitled *The Memoirs of Lord Edward Fitzgerald*, edited with supplementary particulars by Martin MacDermott (1897); R. R. Madden, *The United Irishmen* (7 vols., Dublin, 1842-46); C. H. Teeling, *Personal Narrative of the Irish Rebellion of 1798* (Belfast, 1832); W. J. Fitzpatrick, *The Sham Squire, The Rebellion of Ireland and the Informers of 1798* (Dublin, 1866), and *Secret Service under Pitt* (1892); J. A. Froude, *The English in Ireland in the Eighteenth Century* (3 vols., 1872-74); Ida A. Taylor, *The Life of Lord Edward Fitzgerald* (1903). For particulars of Pamela, and especially as to the question of her parentage, see Gerald Campbell, *Edward and Pamela Fitzgerald* (1904); *Memoirs of Madame de Genlis* (1825); Georgette Ducrest, *Chroniques populaires* (1855); Thomas Moore, *Memoirs of the Life of R. B. Sheridan* (1825).

FITZGERALD, LORD THOMAS (10th earl of Kildare) (1513-1537), known as "Silken Thomas," the eldest son of Gerald Fitzgerald, 9th earl of Kildare, was born in London in 1513. He spent much of his youth in England, but in 1534 when his father was for the third time summoned to England to answer for his maladministration as lord deputy of Ireland, Thomas, at the council held at Drogheda, in February was made vice-deputy. In June the Ormond faction spread a report in Ireland that the earl had been executed in the Tower, and that his son's life was to be attempted. Inflamed with rage at this apparent treachery, Thomas rode at the head of his retainers into Dublin, and before the council for Ireland (June 11, 1534) formally renounced his allegiance to the king and proclaimed a rebellion. His enemies, including Archbishop John Allen (of Dublin), who had been sent by Henry VIII. to watch Fitzgerald, took refuge in Dublin castle. In attempting to escape to England, Allen was taken by the rebels, and was murdered (July 28, 1534) by Fitzgerald's servants in his presence. He was solemnly excommunicated by the Irish Church. Leaving part of his army (with the consent of the citizens) to besiege Dublin castle, Fitzgerald himself went against Piers Butler, earl of Ossory, and succeeded at first in making a truce with him. But the citizens of Dublin now rose against him, Ossory invaded Kildare, and the approach of an English army forced Fitzgerald to raise the siege. Fitzgerald from his stronghold at Maynooth ravaged Kildare and Meath throughout the winter. He succeeded to the earldom of Kildare, on his father's death in the Tower on Dec. 13, 1534, but he does not seem to have been known by that title. On March 23, 1535, the Geraldine stronghold fell and most of the garrison were put to the sword. This proved the final blow to the rebellion. Fitzgerald spent the next few months in raids against the English and their allies, but his party gradually deserting him, on Aug. 18, 1535 he surrendered himself to Lord Leonard Grey (d. 1541), probably on conditions. He was placed in the Tower of London. In February 1536 his five uncles were also, some of them with great injustice, seized and brought to England. The six Geraldines were hanged at Tyburn on Feb. 3, 1537.

FITZGERALD, EDWARD (1809-1883), English writer, translator of Omar Khayyám, was born as EDWARD PURCELL, at Bredfield, Suffolk, on March 31, 1809. His father, John Purcell, who had married a Miss Fitzgerald, assumed in 1818 the name and arms of his wife's family. From 1816 to 1821 the FitzGerald

lived at St. Germain and at Paris, but Edward was educated at Bury St. Edmunds and at Trinity College, Cambridge, where he became acquainted with Thackeray and W. H. Thompson. In 1830 he returned to Paris, but soon chose to settle in the Suffolk town of Woodbridge where he passed a secluded, leisurely life devoted to flowers, music and books. With Tennyson, his intimacy began about 1835 and with Carlyle about 1842. In 1851, Fitzgerald published *Euphranor*, a Platonic dialogue, born of memories of the old happy life at Cambridge. In 1852 appeared *Polonius*, a collection of aphorisms, some original, the rest borrowed from English classics. In the following year he issued *Six Dramas of Calderon*, freely translated, and having turned to Oriental studies under the guidance of his friend E. B. Cowell, afterwards professor of Sanskrit at Cambridge, in 1856 he anonymously published a version of the *Salāmān and Absāl* of Jāmi in Miltonic verse. In the same year he married Lucy, daughter of Bernard Barton, the Quaker poet, but they were soon separated. In Jan. 1859 a little anonymous pamphlet was published as *The Rubdyāt of Omar Khayyām*. The poem seems at first to have attracted no attention, until in 1860 Rossetti discovered it, and Swinburne and Lord Houghton quickly followed. The expression which it gave to the perplexity of the times led to the demand for a second edition in 1868. Meanwhile Fitzgerald had produced in 1865 a version of the *Agamemnon*, and two more plays from Calderon. In 1880-81 he issued privately translations of the two Oedipus tragedies; his last publication was *Readings in Crabbe*, 1882.

From 1861 onwards Fitzgerald's greatest interest centred in the sea, and for some years, till 1871, he spent the months from June to October mainly in "knocking about somewhere outside of Lowestoft." On June 14, 1883, he passed away painlessly in his sleep. He was "an idle fellow, but one whose friendships were more like loves"; his wit and human side are displayed in his inimitable letters. Tennyson's dedication of his *Tiresias* to Fitzgerald's memory, in some touching reminiscent verses to "Old Fitz" (1885) was the signal for the universal appreciation of Omar Khayyām in his English dress. The exquisite melody of Fitzgerald's verse has made the poem probably better known than any single poem of its class published since 1860. (E. G.)

An edition of Fitzgerald's works appeared in 2 vols. (New York, 1887); his *Letters and Literary Remains* were edited by W. Aldis Wright (7 vols., 1902-03); other *Letters* were edited by F. R. Barton (1923), and those to Bernard Quaritch by C. O. Wrenthmore (1926). His *Dict. of Mme. de Sévigné* was edited by his great niece, M. E. F. Kerrich, 2 vols. (1914). See also T. Wright, *Life of E. Fitzgerald*, 2 vols. (1904); A. C. Benson, *E. Fitzgerald* (1905); Morley Adams, *Omar's Interpreter, a New Life of E. Fitzgerald* (1909).

FITZGERALD, GEORGE FRANCIS (1851-1901), Irish physicist, was born at Dublin on Aug. 3, 1851. He studied at Trinity college, Dublin, becoming a fellow in 1877. In 1879 he became tutor and in 1881 Erasmus Smith professor of natural philosophy at Trinity college, Dublin. He retained this post until he died on Feb. 21, 1901. Fitzgerald started classes in experimental physics at Dublin and developed the laboratories in spite of lack of encouragement. He had a wide knowledge of physics and was a brilliant speculator, his services as a critic of scientific work were very much in demand and he had a great influence on the men who worked under him. Fitzgerald's own work is mainly on radiation and electrical theory, most of his papers were published in the *Proceedings* of the Royal Dublin Society and because of this were not as well known as they deserved to be. One of his earliest and most important memoirs on the "Electromagnetic Theory of the Reflection and Refraction of Light" deals with the theoretical bearing of the magneto-optical phenomenon known as the Kerr effect. He investigated the problem of electric radiation due to a variable current and pointed out that the oscillatory discharge of a condenser might be the means of producing electric radiation. Soon after this work appeared Hertz succeeded in producing electric waves experimentally. Fitzgerald realized the importance of this work, he put himself in touch with Hertz and converted him to Maxwell's ideas. He wrote a memoir on the electro-magnetic effect due to the motion of the earth and he constructed a model of the aether.

While studying the results of the Michelson-Morley experiment FitzGerald worked out the change in shape of a body produced by its motion through the aether. This is now known as the Lorentz-FitzGerald hypothesis. In conjunction with his pupils he carried out a number of investigations on the laws of polarization of Hertzian waves by reflection, on the detection of these waves and on the scattering of X-rays; he tested the validity of Ohm's law for electrolysis. In addition to his scientific work FitzGerald was interested in education and it is largely through his efforts that technical education was established in Ireland. He was appointed a commissioner of national education in 1898 and a member of the Irish board of intermediate education in 1900. FitzGerald was a member and officer of many learned societies; he was awarded the Royal Society's Royal medal in 1899.

His papers, with an introduction, have been edited by Larmor under the title *The Scientific Writings of the Late George Francis FitzGerald* (1902).

FITZGERALD, RAYMOND or **REDMOND** (d. c. 1182), surnamed Le Gros, was the son of William Fitzgerald and brother of Odo de Carew. He was sent by Strongbow to Ireland in 1170, and had the chief share in the capture of Waterford and in the successful assault on Dublin. He was sent to Aquitaine to hand over Strongbow's conquests to Henry II., but was back in Dublin in July 1171, when he led one of the sallies from the town. Strongbow offended him later by refusing him the marriage of his sister Basilea, widow of Robert de Quenci, constable of Leinster. Raymond then retired to Wales, and Hervey de Mountmaurice became constable in his place. At the outbreak of a general rebellion against the earl in 1174 Raymond returned with his uncle Meiler Fitz Henry, after receiving a promise of marriage with Basilea. Reinstated as constable he secured a series of successes, and with the fall of Limerick in Oct. 1175 order was restored. Mountmaurice meanwhile obtained Raymond's recall on the ground that his power threatened the royal authority, but the constable was delayed by a fresh outbreak at Limerick, the earl's troop refusing to march without him. On the death of Strongbow he was acting governor until the arrival of William Fitz Aldhelm, to whom he handed over the royal fortresses. He was deprived of his estates near Dublin and Wexford, but the Geraldines secured the recall of Fitz Aldhelm early in 1183, and regained their power and influence. In 1182 he relieved his uncle Robert Fitzstephen, who was besieged in Cork. The date of his death, sometimes stated to be 1182, is not known.

FITZGERALD, a city of southern Georgia, U.S.A., 140m. W. by S. of Savannah; the county seat of Ben Hill county. It is served by the Atlanta, Birmingham and Coast and the Seaboard Air Line railways. The population was 6,870 in 1920 (36% negroes) and was 6,412 in 1930 by the Federal census. The city is a shipping point for cotton, tobacco, peaches, melons, vegetables, lumber, naval stores and other products of the region. It has railroad shops, wood-working plants, cotton mills, cotton-seed oil and peanut-oil mills and other manufacturing industries. FitzGerald was settled in 1895 by a group of Union veterans under the leadership of P. H. Fitzgerald, and was incorporated as a city in 1896. The streets running north and south in the eastern half of the city were named after Northern generals; those in the western half, after Southern generals; and the four drives around the city, after famous battleships.

FITZHERBERT, SIR ANTHONY (1470-1538), English judge, was born at Norbury, Derbyshire, and from 1523 till within a short time of his death in 1538 was justice of the court of common pleas. He is the author of *La Graunde Abridgement*, a digest of important legal cases written in Old French, first printed in 1514; *The Office and Authority of Justices of the Peace*, first printed in 1538 (last ed. 1794); the *New Natura Brevium* (1534, last ed. 1794), with a commentary ascribed to Sir Matthew Hale. To Fitzherbert are sometimes attributed the *Book of Husbandry* (1523), the first published work on agriculture in the English language, and the *Book of Surveying and Improvements* (1523) (see AGRICULTURE).

FITZHERBERT, THOMAS (1552-1640), English Jesuit, was born at Swynnerton, Staffordshire, and educated at Oxford.

In London, he became a member of the association founded in 1580 to assist the Jesuits Campion and Parsons. In 1582 he withdrew to the continent, where he was active in the cause of Mary, queen of Scots. In 1598 he was charged with complicity in a plot to poison Queen Elizabeth. Later he went to Rome, where he was ordained priest (1601-02) and became agent for the English clergy. He was unpopular with them, however, owing to his subservience to the Jesuits, and resigned the agency in 1607. In 1613 he joined the Jesuits and was appointed superior of the English mission at Brussels in 1616, and in 1618 rector of the English college at Rome, where he died on Aug. 7, 1640.

His chief works are:—*A Defence of the Catholycke Cause* (1602); *A Treatise concerning Policy and Religion* (1606-10), and a trans. of Turcellini's *Latin Life of St. Francis Xavier* (1632).

FITZMAURICE, EDMOND GEORGE (1846-), **BARON FITZMAURICE**, son of the 4th Marquess of Lansdowne, was a Liberal in politics, and followed Mr. Gladstone in his home rule policy. As Lord Edmond Fitzmaurice he entered the House of Commons in 1868, and was under-secretary for foreign affairs from 1882 to 1885. He was created Baron Fitzmaurice of Leigh in 1906, and made under-secretary for foreign affairs in Sir Henry Campbell-Bannerman's ministry. In 1908 he became chancellor of the duchy of Lancaster and a member of the Liberal cabinet, but resigned his post in 1909. He wrote biographies of the 1st marquess, of Sir William Petty (1895), and of Lord Granville (1905), under whom he had served at the Foreign Office.

For the 1st marquess, see Lord Fitzmaurice, *Life of William, Earl of Shelburne* (3 vols., London, 1875-76).

FITZMAURICE-KELLY, JAMES (1857-1923), British man of letters, was born in Glasgow. Educated at St. Charles's college, London, he became Taylorian lecturer in Spanish at Oxford in 1902. From 1909 to 1916 he was Gilmour professor of Spanish language and literature at the University of Liverpool; and in 1908 and 1912 Norman MacColl lecturer at Cambridge university. During 1907 and 1908 he lectured for the Hispanic Society of America at various American universities and at London university. In 1916 he was appointed Cervantes professor of Spanish language and literature at the University of London, a post he held till his resignation in 1920. Among his numerous published works should be mentioned *The Life of Miguel de Cervantes Saavedra* (1892); an introduction to the *editio princeps* of *Don Quixote* (1898-99); a *History of Spanish Literature* (1898); *Cervantes in England* (1905); *Miguel de Cervantes: a memoir* (1913); *Cervantes and Shakespeare* (1916); *Góngora* (1918); and *Fray Luis de Leon* (1921). He edited among other publications, the *Oxford Book of Spanish Verse* (1913) and the complete works of Miguel de Cervantes Saavedra (1901, etc.). He died at Sydenham, London, Nov. 30, 1923.

FITZ NEAL or **FITZ NIGEL, RICHARD** (d. 1198), treasurer of Henry II. and Richard I. of England, and bishop of London. His great uncle Roger, bishop of Salisbury, had held the office of treasurer under Henry I. and his father Nigel, under Henry I. and Stephen. Richard, who was born before his father's elevation to the episcopate (1133), succeeded to the office of treasurer in 1158, and held it continuously for 40 years. His name appears in the lists of itinerant justices for 1179 and 1194, but these are the only occasions on which he exercised that office. Before 1184 he became dean of Lincoln and in 1189 Bishop of London.

Richard Fitz Neal's *De necessariis observantiis Scaccarii dialogus*, commonly called the *Dialogus de Scaccario*, is of unique interest to the historian. It is an account, in two books, of the procedure followed by the exchequer in the author's time, a procedure which was largely the creation of his own family. When read in connection with the Pipe Rolls the *Dialogus* furnishes a most faithful and detailed picture of English fiscal arrangements under Henry II. The speakers in the dialogue are Richard himself and an anonymous pupil. The date of the conversation is given in the prologue as 1176-77. This probably marks the date at which the book was begun; it was not completed before 1178 or 1179. Soon after the author's death we find it already recognized as the standard manual for exchequer officials. It was

frequently transcribed and has been used by English antiquarians of every period. Hence it is the more necessary to insist that the historical statements which the treatise contains are sometimes demonstrably erroneous; the author appears to have relied excessively upon oral tradition. Richard Fitz Neal also compiled in his earlier years a register or chronicle of contemporary affairs, arranged in three parallel columns. This was preserved in the exchequer at the time when he wrote the *Dialogus*, but has since disappeared. Stubbs' conjectural identification of this *Liber tricornis* with the first part of the *Gesta Henrici* (formerly attributed to Benedictus Abbas) is now abandoned as untenable.

See Madox's edition in his *History of the Exchequer* (1769); and that of A. Hughes, C. G. Crump and C. Johnson (Oxford, 1902). F. Liebermann's *Einleitung in den Dialogus de Scaccario* (Göttingen, 1875) contains the fullest account of the author.

FITZ-OSBERN, ROGER [ROGER FITZWILLIAM] (fl. 1070), succeeded to the earldom of Hereford and the English estate of William Fitz-Osbern in 1071. In 1075, disregarding William I.'s prohibition, he married his sister Emma to Ralph Guader, earl of Norfolk, at the famous bridal of Norwich, at which the two earls plotted a conspiracy against the king. Roger, who was to bring his force from the west to join the earl of Norfolk, was held in check at the Severn by the King's forces. On the collapse of his confederate's rising, Roger was tried before the Great Council (1075) deprived of his lands and earldom, and sentenced to perpetual imprisonment. He died in prison.

FITZ-OSBERN, WILLIAM, Earl of Hereford (d. 1071), was an intimate friend of William the Conqueror, and the principal agent in preparing for the invasion of England. He was the son of Osbern the seneschal, one of William's guardians during his minority, who had been murdered by the young duke's unruly barons. Fitz-Osbern founded a monastery at Lire about 1042. He became seneschal to the duke, and urged on the plans for the invasion of England. At the Conquest he received the earldom of Hereford with the special duty of pushing into Wales. During William's absence in 1067, English affairs were left in the hands of Fitz-Osbern and of Odo, bishop of Bayeux. Fitz-Osbern also acted as William's lieutenant during the rebellions of 1069. Fitz-Osbern was one of the feudal lords of the Welsh marches, and built several castles for the defence of the border. In 1070 William sent him to assist Queen Matilda in the government of Normandy. But Richilde, widow of Baldwin VI. of Flanders, having offered to marry him if he would protect her son Arnulf against Robert the Frisian, Fitz-Osbern accepted the proposal and joined Richilde in Flanders. He was killed, fighting against Robert, at Cassel in 1071.

See E. A. Freeman, *Norman Conquest*, vols. iii. and iv. (1867-79); Sir J. Ramsey, *Foundations of England*, vol. ii. (1898).

FITZ OSBERT, WILLIAM (d. 1196), was a Londoner who had served in the Third Crusade, and on his return took up the cause of the poorer citizens against the magnates who monopolized the government of London. He complained in particular of the unfair assessments of the "aids" for the king's ransom (1194). The chronicler Roger of Hoveden gives Fitz Osbert a high character, and he was implicitly trusted by the poorer citizens. He attempted to procure redress for them from the king; but the city magistrates persuaded the justiciar Hubert Walter that Fitz Osbert was planning a general rising. The troops were sent to seize the demagogue, smoked him out of the sanctuary of St. Mary-le-Bow, in which he had taken refuge, and dragged him to the Tower where he was sentenced to death. He was hanged in chains at Smithfield on April 6, 1196 with nine of his followers.

FITZ PETER, GEOFFREY (d. 1213), earl of Essex and chief justiciar of England, was a sheriff, a justice itinerant and a justice of the forest under Henry II. During Richard's absence on crusade he was one of the five justices of the king's court who stood next in authority to the regent, Longchamp. In 1190 Fitz Peter succeeded to the earldom of Essex, in the right of his wife, who was descended from the famous Geoffrey

de Mandeville. In attempting to assert his hereditary rights over Walden priory Fitz Peter came into conflict with Longchamp, and revenged himself by joining in the baronial agitation through which the regent was expelled from his office. Though refusing to give him formal investiture of the Essex earldom, Richard appointed him justiciar in succession to Hubert Walter (1198). Fitz Peter continued Walter's policy of encouraging foreign trade and the development of the towns; many of the latter received, during his administration, charters of self-government. He was continued in his office by John, who found him an able instrument of extortion. He profited to no small extent by the spoliation of church lands in the period of the interdict. But he was not altogether trusted by the king. The contemporary *Histoire des ducs* describes Fitz Peter as living in constant dread of disgrace and confiscation. In the last years of his life he endeavoured to act as a mediator between the king and the opposition. It was by his mouth that the king promised to the nation the laws of Henry I. (at the council of St. Albans, Aug. 4, 1213). But Fitz Peter died a few weeks later (Oct. 2). Fitz Peter was neither a far-sighted nor a disinterested statesman; but he was the ablest pupil of Hubert Walter, and maintained the traditions of the great bureaucracy which the first and second Henries had founded.

See the original authorities specified for the reigns of Richard I. and John. Also Miss K. Norgate's *Angevin England*, vol. ii. (1887) and John Lackland (1902); A. Ballard in *English Historical Review*, xiv. p. 93; H. W. C. Davis, *England under the Normans and Angevins* (1905).

FITZROY, ROBERT (1805-1865), English vice-admiral, hydrographer and meteorologist, was born at Ampton Hall, Suffolk, on July 5, 1805, being a grandson on the father's side of the third duke of Grafton, and, on the mother's, of the first Marquis of Londonderry. He entered the navy in 1819. After service in the Mediterranean and on the South American station he was promoted in 1828 to the command of the "Beagle," a brig of 240 tons, which was employed on the survey of the coasts of Patagonia and Terra del Fuego. She returned in 1830, and Fitzroy brought with him four Fuegians. One of them died after reaching England; the others he took back the next year, when he was reappointed to the "Beagle" to continue the survey. She sailed from Plymouth on Dec. 27, 1831, carrying as a supernumerary Charles Darwin. On Oct. 2, 1836, she reached Falmouth again, having surveyed the Straits of Magellan and part of the coast of South America, and run a chronometric line round the world. In 1839 Fitzroy published in two volumes *Narrative of the . . . Voyages of H.M.S.S. Adventure and Beagle, etc.*, with a third volume by Darwin. In 1843 he became member of parliament for Durham and was appointed conservator of the Mersey. Early in 1843 he was appointed governor and commander-in-chief of New Zealand. His policy favoured the natives, and the settlers secured his recall in Nov. 1845. After serving as superintendent of Woolwich Dockyard, and in command of the "Arrogant," an experimental screw frigate fitted out under his supervision, he was placed on half-pay in 1850. In 1854 he was appointed chief of the newly formed meteorological department of the Board of Trade, and henceforward his career was devoted to practical meteorology. In 1863 he published his *Weather Book*; the views in it are far in advance of his time, and his system of observations of storm warnings is the basis of that in use to-day. He also reduced to a practical form the wind charts of Capt. Maury. His last years were devoted to the Lifeboat Association. This work overstrained his health, and he committed suicide on April 30, 1865.

His other Publications are: *Remarks on New Zealand* (London, 1846); *Sailing Directions for South America* (London, 1848); and occasional papers in the *Journal* of the R.G.S. See Symon's *Monthly Meteorological Magazine*, No. 33, pp. 161-164 (1898), and Biographical notes and portrait in *Marine Observer*, i., 50-52 (1924).

FITZROY, a north-eastern suburb of Melbourne, Australia (q.v.). It is a manufacturing centre.

FITZ STEPHEN, ROBERT (fl. 1150), son of Nesta, a Welsh princess and former mistress of Henry I., by Stephen, constable of Cardigan, whom Robert succeeded in that office, took service with Dermot of Leinster when that king visited

England (1167). In 1169 Robert led the vanguard of Dermot's Anglo-Welsh auxiliaries to Ireland, and captured Wexford, which he was then allowed to hold jointly with Maurice Fitz Gerald. Taken prisoner by the Irish in 1171, he was by them surrendered to Henry II., who appointed him lieutenant of the justiciar of Ireland, Hugh de Lacy. Robert rendered good service in the troubles of 1173, and was rewarded by receiving, jointly with Miles-Cogan, a grant of Cork (1177). He had difficulty in maintaining his position and was nearly overwhelmed by a rising of Desmond in 1182. It has been surmised that he died in 1183.

FITZ STEPHEN, WILLIAM (d. c. 1190), biographer of Thomas Becket and justice itinerant, was born in London. He entered Becket's service between 1154 and 1162. The chancellor employed him in legal work, made him sub-deacon of his chapel and treated him as a confidant. Fitz Stephen appeared with Becket at the council of Northampton (1164) when the disgrace of the archbishop was published to the world; but he did not follow Becket into exile. He joined Becket's household again in 1170, and was a spectator of the tragedy in Canterbury cathedral. His life of Becket is the most valuable we have. Though he writes as a partisan he gives a precise account of the differences between Becket and the king. It also contains a description of London which is our chief authority for the social life of the city in the 12th century. Despite his connection with Becket, William was sheriff of Gloucestershire from 1171 to 1190, and a royal justice in the years 1176-80 and 1189-90.

See his "Vita S. Thomae" in J. C. Robertson's *Materials for the History of Thomas Becket*, vol. iii. (Rolls series, 1877). Sir T. D. Hardy, in his *Catalogue of Materials*, ii. 330 (Rolls series, 1865), discusses the manuscripts of this biography and its value. W. H. Hutton, *St. Thomas of Canterbury*, pp. 272-274 (1889), gives an account of the author.

FITZ THEDMAR, ARNOLD (1201-1274), London chronicler and merchant, was born in London, Aug. 9, 1201, of parents whose families had come to London from Germany. He became, as he tells us, alderman of a London ward and an active partisan in municipal politics. In the Barons' War he took the royal side against the populace and the mayor, Thomas Fitz Thomas. The popular party planned, in 1265, to try him for his life before the folk-moot, but he was saved by the news of the battle of Evesham which arrived on the very day appointed for the trial. In 1270 he was one of the four citizens to whom the muniments of the city were entrusted. To this we probably owe the compilation of his chronicle, *Chronica Maiorum et Vicecomitum*, which begins at the year 1188 and is continued to 1274. From 1239 onwards this work is a mine of curious information. Though municipal in its outlook, it is valuable for the general history of the kingdom, owing to the important part which London played in the agitation against the misrule of Henry III. Arnold was by no means blind to the faults of Henry's government, but preferred an autocracy to the mob-rule which Simon de Montfort countenanced in London.

The *Chronica Maiorum et Vicecomitum*, with the other contents of Arnold's commonplace book, were edited for the Camden Society by T. Stapleton (1846), under the title *Liber de Antiquis Legibus*. Our knowledge of Arnold's life comes from the *Chronica* and his own biographical notes. Extracts, with valuable notes, are edited in G. H. Pertz's *Mon. Germaniae historica, Scriptores*, vol. xxviii. See also J. M. Lappenbergs *Urkundliche Geschichte des Händelschen Stahlhofes zu London* (Hamburg, 1851).

FITZWALTER, ROBERT (d. 1235), leader of the baronial opposition against King John of England, served John in the Norman wars, and was taken prisoner by Philip of France, and forced to pay a heavy ransom. He was implicated in the baronial conspiracy of 1212. He was outlawed, but returned under a special amnesty after John's reconciliation with the pope. He continued, however, to take the lead in the baronial agitation against the king, and upon the outbreak of hostilities was elected "marshal of the army of God and Holy Church" (1215). He secured the support of the city of London. The famous clause of Magna Carta (§ 39) prohibiting sentences of exile, except as the result of a lawful trial, refers more particularly to his case. He was one of the 25 appointed to enforce the promises of Magna Carta; and his aggressive attitude was one of the causes which contributed to the recrudescence of civil

war (1215). He was one of the envoys who invited Louis to England, and was the first of the barons to do homage when the prince entered London. Though slighted by the French as a traitor to his natural lord, he served Louis with fidelity until he was captured at the battle of Lincoln (May 1217). Released on the conclusion of peace he joined the Damietta crusade of 1219, but returned at an early date to make his peace with the regency.

BIBLIOGRAPHY.—The *Histoire des ducs de Normandie et des rois d'Angleterre* (ed. F. Michel, 1840) gives the fullest account of his quarrel with the king. See also Miss K. Norgate's *John Lackland* (1902), W. McKechnie's *Magna Carta* (1905), and Stubbs's *Constitutional History*, vol. i. ch. xii. (1897).

FITZWILLIAM, WILLIAM WENTWORTH FITZWILLIAM, 2ND EARL (1748-1833), English statesman, was the son of the 1st earl (U.K. peerage), who died in 1756. The English family of Fitzwilliam claimed descent from a natural son of William the Conqueror, and among its earlier members were a Sir William Fitzwilliam (1460-1534), sheriff of London, who in 1506 acquired the family seat of Milton Manor in Northamptonshire, and his grandson Sir William Fitzwilliam (see below). The latter's grandson was made an Irish baron in 1620; and in later generations the Irish titles of Viscount Milton and Earl Fitzwilliam (1716) and the English titles of Baron Milton (1742) and Viscount Milton and Earl Fitzwilliam (1746), were added. These were all in the English house of the Fitzwilliams of Milton Manor. They were distinct from the Irish Fitzwilliams of Meryon, who descended from a member of the English family who went to Ireland with Prince John at the end of the 12th century, and whose titles of Baron and Viscount Fitzwilliam died out with the 8th viscount in 1833; the best known of these was Richard, 7th viscount (1745-1816), who left the Fitzwilliam library and a fund for creating the Fitzwilliam Museum to Cambridge university.

The 2nd earl inherited not only the Fitzwilliam estates in Northamptonshire, but also, on the death of his uncle, the marquess of Rockingham, in 1782, the valuable Wentworth estates in Yorkshire, and thus became one of the wealthiest noblemen of the day. He was an active supporter of the Whig party; and in 1794, with other "old Whigs," joined Pitt's cabinet, becoming president of the council. At the end of the year, however, he was sent to Ireland as viceroy. Fitzwilliam, however, had set his face against the jobbery of the Protestant leaders, and threw himself warmly into Grattan's scheme for admitting the Catholics to political power; and in March 1795 he was recalled, his action being disavowed by Pitt, the result of a series of misunderstandings which appeared to Fitzwilliam to give him just cause of complaint. In 1806 he was president of the council, but his Whig opinions kept him mainly in opposition. He died in February 1833, his son, Charles William Wentworth, the 3rd earl (1786-1857), and later earls, being notable figures in the politics and social life of the north of England.

FITZWILLIAM, SIR WILLIAM (1526-1599), lord deputy of Ireland, was the eldest son of Sir William Fitzwilliam (d. 1576) of Milton, Northamptonshire, where he was born. In 1559 he became vice-treasurer of Ireland and a member of the Irish House of Commons; and between this date and 1571 he was (during the absences of Thomas Radclyffe, earl of Sussex, and of his successor, Sir Henry Sidney) five times lord justice of Ireland. In 1571 Fitzwilliam himself was appointed lord deputy, but like Elizabeth's other servants he received little or no money, and his period of government was marked by continuous penury and its attendant evils, inefficiency, mutiny and general lawlessness. Moreover, the deputy quarrelled with the lord president of Connaught, Sir Edward Fitton (1527-1579), but he compelled the earl of Desmond to submit in 1574. Returning to England in 1575 he was governor of Fotheringhay Castle at the time of Mary Stuart's execution. In 1588 Fitzwilliam was again in Ireland as lord deputy, and although old and ill he displayed great activity in leading expeditions, and found time to quarrel with Sir Richard Bingham (1528-1599), the new president of Connaught. In 1594 he finally left Ireland, and five years later he died at Milton. From Fitzwilliam, whose wife was Anne, daughter of Sir William Sidney, were descended the barons and earls Fitzwilliam.

See R. Bagwell, *Ireland under the Tudors*, vol. ii. (1885).

FITZWILLIAM MUSEUM, a building erected to house the collection of music, books, paintings and other works of art. bequeathed in 1816 by Richard, Viscount Fitzwilliam, to the University of Cambridge, England. Both the collection and the buildings have been greatly enlarged by the bequest of Charles Brinsley Marlay in 1912, and the gifts of two anonymous benefactors.

FIUGGI, a town of Italy, province of Frosinone, Lazio, 50 m. S.E. of Rome by rail, 2,450 ft. above sea level. Pop. (1921), 2,801, town; 3,515, commune. The town, which lies on a hill, was known as Anticoli di Campagna till 1911, but has recently taken the name of the springs some 400 ft. lower down, which have made it into a resort of considerable importance in summer. The water is cold, quite tasteless, and is said to have the lowest mineral content of any known spring water, and to possess considerable radio-active properties.

FIUME, Adriatic port, capital of the Italian Provincia del Carnaro, on the north of the Gulf of Quarnero, 70 m. S.E. of Trieste. Pop. (1926), 46,063. After being taken by Charlemagne it long remained under the Franks and was then held by the bishop of Pola in feudal tenure from the patriarch of Aquileia. The counts of Duino held it 1139-c. 1400. The counts of Wallace held it next, and in 1471 emperor Frederick III. incorporated it in Austria; it was made a free port in 1723 and was united to Croatia in 1776 and declared a *corpus separatum* of the Hungarian Crown in 1779. The French held it 1809-13, when the English took it and restored it to Austria in 1814. It was ceded to Hungary in 1822, was Croatia's in 1849-70, and thereafter under Hungary until it sprang into world-wide notoriety in connection with the matters discussed below.

The town is built on a ridge of the Karst, while the newer parts are crowded into the amphitheatre between ridge and shore. The old town has a 3rd century Roman triumphal arch. The cathedral of the Assumption was founded in 1377. The Pilgrimage church hung with offerings from shipwrecked sailors is approached by a stairway of 400 steps. The Maria Theresa road was opened in 1809 to connect Fiume with Hungary via Karolyváros or Karlstadt (Croatia). There are two railways, one connecting with Trieste and Ljubljana, and the other running through Croatia to Zagreb. The soil around Fiume is stony, but the climate favours the vine; the gulf yields abundant fish, especially tunny. When Fiume was included in Hungary, it was a port of emigration, and had a torpedo factory. Many Italian immigrants entered Fiume before 1914, and the pop. (1910) was 22,488 Italians and 13,351 Slavs, as well as Hungarians, Germans and others; the suburb, Susak or Sushak, had an estimated population of 1,500 Italians and 11,000 Slavs, and others.

The main harbour is formed within a long breakwater. The entrance is deep and there are 27-30 ft. of water at the quays. A floating dock of 1,800 tons lifting capacity is part of the equipment. Wood, rice, sugar, petrol are exported, and fuels and colonial articles, including rice, are imported. (X.)

THE 20TH CENTURY

Fiume became a burning question after the World War. It even threatened to become the cause of a further war between Italy and Yugoslavia, although the secret treaty of London of April 26, 1915, which contained Italy's terms for entering into the War, assigned Fiume to Croatia.

The Italian Claims.—The first Italian claim to Fiume was made by Bissolati (*q.v.*) immediately after his resignation from the cabinet at the end of 1918. Baron Sonnino's inaction in this matter was due to the fact that in 1915 he had neither anticipated, nor desired, the total break-up of the dual monarchy. But in 1919 the official Italians demanded Fiume on the principle of "self-determination," because its Italian inhabitants were in the majority, and in a larger majority still if Fiume proper were separated from its Yugoslav suburb of Sušak on the opposite side of the rivulet, which had given to Fiume its name, and which the Slavs called simply Rečina, and the Italians Eneo. That Fiume was in 1919 predominantly Italian is true, but the Italian element had largely immigrated within comparatively recent years.

Meanwhile, on Oct. 23, 1918, Croat troops had seized Fiume

and in November there was a dual occupation, against which the Yugoslav national council protested, by Italian and Serbian troops, while Italian naval forces entered the harbour. The Serbian troops were, however, withdrawn and replaced by an inter-Allied force, pending the decision of the Fiume question by the Peace Conference. The Italians' position was similar to that known in English law as "pleading inconsistent defences." They claimed North Dalmatia, overwhelmingly Slav by race, in virtue of the Treaty of London, which President Wilson repudiated, and Fiume in virtue of the Wilson principle of "self-determination."

The D'Annunzio Adventure.—They ultimately obtained Fiume, thanks to the raid made by Gabriele D'Annunzio (*q.v.*), who mustered a body of men at Ronchi near Trieste, and on Sept. 12, 1919, occupied the contested town. There, despite official notes, he remained as "commandant." He drew up a constitution for the "Carnaro," as he called his miniature state. He descended with his "legionaries" upon Zara and meditated an extension of his territories still farther southward. While successive Italian governments gave him no official support, he received considerable sympathy from the nationalist elements in Italy. But when Signor Giolitti in 1920 became for the last time premier and concluded the Treaty of Rapallo with the Yugoslavs, he resolved to turn the poet out of Fiume. The "commandant's" official residence was bombarded by the "Andrea Doria," and he narrowly escaped the martyrdom which he had proclaimed for himself and his followers. After the "heroic age" of his rule there came the prosaic interlude of his local rival, Signor Zanella, who represented the autonomous, as opposed to the Italian national party, and aimed at bringing about a good understanding with Yugoslavia. A *coup d'état* by *Fascisti* and "legionaries" took place in 1922; the government offices were stormed; Signor Zanella abdicated in favour of a "government of national defence," and was escorted over the frontier in an armoured car; Signor Prodan, a local engineer, succeeded him, and annexation to Italy was proclaimed. Official Italy, however, acted with caution and persuaded Signor Giurati, a *Fascista* deputy, to decline the proffered post of "civil commissioner," while D'Annunzio from his retreat on the lake of Garda denounced the dissensions of Fiume, and refused to return and lead the Fiuman movement.

Negotiations Between Italy and Yugoslavia.—Finally, General Giardino became governor, and Signor Mussolini made a serious attempt to come to terms with the Yugoslavs. The river had in the course of generations changed its course, forming a "delta," as it was called, and thus rendering doubtful the boundary of Fiume towards Sušak. Both parties claimed the "delta." The smaller harbour, too, called in Hungarian times "Port Baross" after a former governor, but re-christened by the Italians "Porto Nazario Sauro" after one of the heroes of the War, was a matter of dispute, but by a letter written by Count Sforza, then Italian minister of foreign affairs, a few hours after the signature of the treaty of Rapallo in Nov. 1920 it was ceded to Yugoslavia.

Even after the refusal of D'Annunzio the two rival races did their best to give one another economic pin-pricks and thereby nearly ruined the trade of the once flourishing port of Hungary. But at last a series of arrangements was concluded at Rome between the Italian and Yugoslav governments on Jan. 27, 1924. Fiume, with the larger harbour, was definitely recognized as Italian; Porto Baross and "the delta" was left to Yugoslavia, and through railway traffic, after several years' intermission, was renewed. But the Fiuman frontier towards the north is fantastic, for a mere corridor, through which the road and railway run, connects the town with Abbazia, and is commanded by the old Roman fortress of Castua. The opening (in Aug. 1925) of the last link in the Lika railway connecting Spalato with the Yugoslav hinterland is a fresh blow to Fiume, while the old Hungarian-Croatian steamship line now rechristened "Jadranska Plovidba" ("Adriatic Steamship Co.") starts from Port Baross and boycotts Italian Zara. An Italo-Hungarian convention providing for a Free Zone at Fiume for the benefit of Hungary was signed in Rome on July 25, 1927, and negotiations for its formation were initiated in the following October.

FIVE NATIONS: see IROQUOIS.

FIVES. A ball game played by two or four players in a court enclosed on three or four sides, the ball being struck with the hand usually protected by a glove. Certain forms of the game in the United States, in Ireland and in some parts of the north of England are known as handball (*q.v.*). The origin of the game is probably the *Jeu de Paume*. The derivation of the word *fives* is doubtful. It may be from *Longue Paume* in which five on a side played or from the five fingers or that the winners formerly had to make five points. There were buildings known as *fives* courts before the middle of the 18th century and the word *fives* was then applicable to games played both with the hand and with a racket or bat. (Bat *fives* is still played at a number of British public schools.) There are three forms of hand *fives* in Great Britain which require separate notice. Eton *fives*, Rugby *fives* and Winchester *fives*. These games are chiefly played at public schools but there are a few other courts to be found in various parts of the country. In Nov. 1927, an Eton *fives* court covered in and artificially lighted was opened at Queen's club. Among the schools which play Eton *fives* in addition of course to Eton, where the game was invented, are Harrow, Charterhouse, Shrewsbury, Repton, Uppingham, Aldenham and Highgate. Among those which play Rugby *fives* are Rugby, Marlborough, Clifton, Cheltenham, Haileybury and St. Paul's. Winchester *fives* courts are few and far between but there are one or two other schools beside Winchester which have them. There is a *Fives* Association which is affiliated to the Tennis and Rackets Association. In 1925 two open competitions, one for Eton *fives* and one for Rugby *fives* were started, but the next year they were allowed to lapse. In 1928, however, they were restarted.

Eton Fives.—The peculiar features of the Eton court arose from the fact that in early times the game was played against the chapel-wall, so that buttresses formed side walls and the balustrade of the chapel-steps projected into the court, while a step divided the court latitudinally. These were reproduced in the regular courts, the buttress being known as the "pepperbox" and the space between it and the step as the "hole." The riser of the step is about 5 in. The floor of the court is paved; there is no back wall. On the front wall is a ledge, known as the "line," 4 ft. 6 in. from the floor, and a vertical line, painted, 3 ft. 8 in. from the right-hand wall. Four people usually play, two against two; one of each pair plays in the forward court, the other in the back court. The server stands on the left of the forward court, his partner in the right-hand corner of the back court; the taker of the service by the right wall of the forward court, his partner at the left-hand corner of the back court. The forward court is known as "on-wall," the other as "off-wall." The server must toss the ball gently against the front wall, above the line, so that it afterwards hits the right wall and falls on the "off-wall," but the server's object is not, as at tennis and rackets, to send a service that cannot be returned. At *fives* he must send a service that hand-out can take easily; indeed hand-out can refuse to take any service that he does not like, and if he fails to return the ball above the line no stroke is counted. After the service has been returned either of the opponents returns the ball if he can, and so on, each side and either member of it returning the ball above the line alternately till one side or the other hits it below the line or out of court. Only hand-in can score. If hand-in wins a stroke, his side scores a point; if he misses a stroke he loses his innings and his partner becomes server, unless he has already served in this round, in which case the opponents become hand-in. The game is 15 points. If the score is "13 all," the out side may "set" the game to five or three, *i.e.*, the game becomes one of five or three points; at "14 all" it may be set to three. The game and its terminology being somewhat intricate, can best be learnt in the court. No apparatus is required except padded gloves and *fives*-balls, which are covered with white leather tightly stretched over a hard foundation of cork, strips of leather and twine. The Eton balls are 1½ in. in diameter and weigh about 1½

oz. apiece.

Rugby *Fives* is much less complicated owing to the simpler form of the court. This is a four-walled building with no hazard of any kind. There are also a few courts which have no back wall. The court is larger than an Eton court. No standard dimensions have been issued. A play board is fixed on the front wall, about 34 in. from the ground. The ball is rather smaller than that in use at Eton *fives*. The rules as to return of service, taking balls, etc., are similar to those at Eton *fives*.

Winchester *Fives* is like Rugby *fives* in nearly every particular except that in the left-hand wall of the Winchester court there is a small buttress built on the same lines as a tambour in the tennis court.

See *Tennis, Rackets and Fives* in the All England Series (1890); official *Handball Guide* in Spalding's Athletic Library; *Winchester Fives* by an old Wykehamist (P. and G. Wells, Winchester); Gaelic Athletic Association, *Playing Rules of Football, Hurling, Rounders and Handball*. (E. B. N.)

FIXED ASSETS, also known as capital assets, are assets (*q.v.*) of a lasting nature which are acquired for the purpose of carrying on a business and which are intended as a permanent investment. Such assets as land, buildings, machinery and equipment, furniture and fixtures, patterns, drawings and durable tools are included in this group. Ordinarily, securities such as stocks, bonds and long term notes are also regarded as fixed assets. This is notably true if these securities represent holdings in affiliated companies. If they do not, and if they might be disposed of without interference with the operation of the business, they may be grouped under "other" or "miscellaneous" assets. The practice of including the capitalized value of patents, trade-marks and goodwill in the fixed assets is open to attack; usually, tangible assets only are included.

FIXED PRICE. A term sometimes applied to a price fixed and maintained by mutual agreement between wholesale producers and retail distributors. In a majority of cases such fixed prices are arranged by big producing firms as a condition of supply for retailing, *i.e.*, the producer binds the retailer not to sell his goods under a certain agreed price. In other cases, agreements of this sort are arrived at between combinations of producers on the one hand and combinations of retailers on the other hand. (See PRICE MAINTENANCE.)

FIXTURES, in law, chattels which have been so fixed or attached to land (as it is expressed in English law, "so annexed to the freehold"), as to become, in contemplation of law, a part of it. All systems of law make a marked distinction, for certain purposes, between immovables and movables, between real and personal property, between land and all other things. In the case of fixtures the question arises under which set of rights they are to fall—under those of real or of personal property. The general rule of English law is that everything attached to the land goes with the land—*quicquid plantatur solo, solo cedit*. The rigour of this rule has been modified by a large number of exceptions formulated from time to time by the courts as occasion arose.

In order to constitute a fixture there must be some degree of annexation to the land, or to a building which forms part of it. Thus it has been held that a barn laid on blocks of timber but not fixed to the ground itself is not a fixture, and the onus of showing that articles not otherwise attached to the land than by their own weight have ceased to be chattels rests with those who assert the fact. On the other hand, an article, even slightly affixed to the land, is to be considered part of it, unless the circumstances show that it was intended to remain a chattel. The question is one of fact in each case—depending mainly on the mode, degree, and object of the annexation and the possibility of the removal of the article without injury to itself or the freehold. In certain cases the courts have recognized a constructive annexation, when the articles, though not fixed to the soil, pass with the freehold as if they were, *e.g.*, the keys of a house, the stones of a dry wall, and the detached or duplicate portions of machines. For the lease of a house the term "fixture" means something affixed to the premises after the structure was completed and does not include things forming part of the original structure. (*Boswell v. Crucible Steel Co.*, 1925, 1 K.B. 119.)

Questions as to the property in fixtures principally arise—(1) between landlord and tenant, (2) between heir and executor, (3) between executor and remainder-man or reversioner, (4) between seller and buyer.

(1) At common law, if the tenant has affixed anything to the freehold during his occupation, he cannot remove it without the permission of his landlord. But an exception was established in favour of *trade fixtures*. It may be stated as a general rule that things which a tenant has fixed to the freehold for the purpose of trade or manufacture may be taken away by him, whenever the removal is not contrary to any prevailing practice or the particular terms of the contract of tenancy, and can be effected without causing material injury to the estate or destroying the essential character of the articles themselves (*Lambourn v. McLellan* 1903, 2 Ch. 269). Agricultural tenants were not entitled, at common law, to remove trade fixtures. But the Landlord and Tenant Act 1851 granted such a right of removal in the case of buildings or machinery erected by a tenant at his own expense, and with his landlord's consent in writing, provided that the freehold was not injured or that any injury was made good, and that before removal a month's written notice was given to the landlord, who had an option of purchase. Under the Agricultural Holdings Act 1923 fixtures erected by the tenant are removable by him, within a reasonable time after the termination of the tenancy, subject to the landlord not electing to take them over at a valuation (s. 22). These provisions apply to market gardens; as to allotments see the Allotments Act 1922 and ALLOTMENTS and SMALL HOLDINGS.

Again, *ornamental* fixtures set up by the tenant for ornament and convenience, such as hangings and looking-glasses, tapestry, iron backs to chimneys, wainscot fixed by screws, marble chimney pieces, are held to belong to the tenant and to be removable without the landlord's consent. Here again the extent of the privilege has been a matter of some uncertainty.

In all these cases the fixtures must be removed during the term. The tenant's right to the fixtures is not, however, destroyed by the mere expiry of the term if he still remains in possession; but if he has once left the premises he cannot come back and claim his fixtures. The theft by a tenant or lodger, or the husband or wife of any tenant or lodger, of any fixture left to be used by any such person in or with any house or lodging is a felony. (Larceny Act 1916, s. 16.)

(2) As between heir and executor or administrator. The question of fixtures arises between these parties on the death of a person owning land. The executor has no right to remove trade fixtures set up for the benefit of the inheritance. As regards ornamental objects, the rule *quicquid plantatur solo, solo cedit*, was in early times somewhat relaxed in favour of the executor. As far back as 1701 it was held that hangings fixed to a wall for ornament passed to the executor; and, although the effect of this relaxation was subsequently cut down, it is supported by the decisions of the courts affirming the executor's right to valuable tapestries affixed by a tenant for life to the walls of a house for ornament and their better enjoyment as chattels (*Leigh v. Taylor*, 1902 App. Cas. 157; and see *In re Hulse* 1905, Ch. 406); and the same has been held as to statues and bronze groups set on pedestals in the grounds of a mansion house.

(3) When a tenant for life of land dies the question of fixtures arises between his representatives and the persons next entitled to the estate (the remainder-man or reversioner). The remainder-man is not so great a favourite of the law as the heir, and the right to fixtures is construed more favourably for executors than in the preceding cases between heir and executor. Whatever are executor's fixtures against the heir would therefore be executor's fixtures against the remainder-man. Agricultural fixtures are not removable by the executor of a tenant for life.

(4) As between seller and buyer, a purchase of the lands includes a purchase of all the fixtures. But here the intention of the parties is of great importance. Similar questions may arise in other cases, e.g., as between mortgagor and mortgagee. The question of what is or is not a fixture must also often be considered in questions of rating or assessment. A sale of settled land may be made subject to a stipulation that fixtures shall be taken by the pur-

chaser at a valuation, and the amount of such valuation is part of the price of the land and forms "capital money" accordingly. See the Settled Land Act 1925, s. 49 (2).

The law of Scotland as to fixtures is the same as that of England. The Agricultural Holdings (Scotland) Act 1923, s. 29 and, as to market gardens, s. 42, gives a similar statutory right of removal. The law of Ireland has been the subject of special legislation. (See LANDLORD AND TENANT.) The French Code Civil recognizes the right of the usufructuary to remove articles attached by him to the subject of his estate on the expiry of his term, on making good the place from which they were taken (Art. 599); and there are similar provisions in the Civil Codes of Italy (Art. 495), Spain (Arts. 487, 489), and Germany (Arts. 1037, 1049). Certain classes of movables are treated in law as immovable by destination and pass with the land as such. See Burge, *Col. and For. Laws*, 2nd ed. IV. pt. I. 644.

The law of the United States as to fixtures is substantially identical with English common law. Constructive, as well as actual, annexation is recognized. The same relaxations (from the common law rule *quicquid plantatur solo, solo cedit*) as regards trade fixtures and ornamental fixtures, such as tapestry, have been recognized.

In Mauritius the provisions of the Code Civil are in force without modification. In Quebec (Civil Code, Arts. 374 *et seq.*) and St. Lucia (Civil Code, Arts. 368, *et seq.*) they have been re-enacted in substance. Some of the British colonies have conferred on tenants a statutory right to remove fixtures.

FIZEAU, ARMAND HIPPOLYTE LOUIS (1819–1896), French physicist, was born at Paris on Sept. 23, 1819. As he was wealthy he was able to follow his inclinations and devote himself to experimental work in physics. Between 1845 and 1849 he worked in conjunction with Foucault (*q.v.*). They investigated the infra-red portion of the solar spectrum, and made other observations, in heat and light. In 1849 Fizeau published the results of his experiments on the velocity of light (*q.v.*); he gave the first reliable value of this velocity by a terrestrial method, and the correct explanation of the Doppler principle (see LIGHT: *Waves and Interference*), as applied to the light coming from a star (*q.v.*), and showed how it could be used to measure the relative velocities of stars in the line of sight. In 1851 he carried out a series of experiments on the velocity of light in a moving medium, and measured the shift of interference fringes due to light passing through a column of moving water. These experiments were designed to see if any relative motion of aether and matter could be detected (see ETHER). Later experiments describe the use of a condenser for increasing the efficiency of an induction coil and the application of interference methods for measuring the expansion of crystals. He became a member of the French Academy in 1860 and of the Bureau des Longitudes in 1878; in 1863 he was appointed inspecteur de physique at the École Polytechnique, Paris. He died at Venteuil on Sept. 18, 1896.

FJORD or **FIORD** (fyawrd) is the name given to a narrow arm of the sea which runs far inland and with more or less precipitous sides. The term is of Norwegian origin and is the name given to the characteristic sea lochs of the coast-line of that country. Fiords differ from normal river estuaries in that their channels are long straight and narrow, with steep parallel sides which plunge far below the level of the water, and from which side arms of a similar shape branch off at constant angles. Fiords are remarkable for their depth, Messier Channel (Patagonia) is 4,250 ft. deep, and Sogne Fiord (Norway) is 100 m. long and 4,000 ft. deep, but their deepest portion is always at some distance from the sea very shallow water occurring at their mouths. Loch Moran (Inverness, depth 1,017 ft.) is a typical fiord but is separated from the sea by land 30 ft. above sea

level. Fiords lie in deeply dissected plateau lands so that above the precipitous walls are gentle slopes and wide valleys. J. W. Gregory (see *Nature and Origin of Fiords*, London, 1913) distinguishes three types of sea estuaries, *fiords*, as here described, *rias* and *fjords*.

Several theories have been put forward to explain the formation of fiords. A controlling factor in the formation of these theories has been the distribution of fiords and their occurrence in recently glaciated regions. Fiords do not occur widespread but appear to be situated around the polar regions, in Norway, the west coasts of Scotland, Ireland and Iceland, Greenland, Alaska and British Columbia, in Patagonia, the south of New Zealand and in several Antarctic lands. Sea erosion, glacial action or river denudation are not sufficient of themselves to account for the phenomena. The most probable process appears to have been as follows. Fiords occur in regions which have suffered faulting within geologically recent times, the faults being numerous and generally in more than one direction. Such faulting occurred in regions of tension and was accompanied by regional uplift, and in consequence river activity was increased and quickly reduced to base level a new river system which followed the lines of weakness set up by the faulting. The uplift and faulting took place before the Glacial Period, probably during the Pliocene, so that glaciers as well as rivers have played their part in fiord formation and modification. The latest stage has been subsidence and in some places tilting and the drowning of the river valleys by the incursion of the sea. Fiord coastlines are noted for their beauty. In the past they have provided an easy—frequently the only—means of communication for the people in many districts and have therefore played an important part in the development of racial and national characteristics.

FLACCUS, a cognomen in the plebeian gens Fulvia, one of the most illustrious in ancient Rome. Cicero and Pliny state that the family came from Tusculum, where some were still living in the middle of the 1st century B.C. Of the Fulvii Flacci the most important were the following:

QUINTUS FULVIUS FLACCUS, son of the first of the family, Marcus, who was consul with Appius Claudius Caudex in 264 B.C. He especially distinguished himself during the second Punic War. He was consul four times (237, 224, 212, 209), censor (231) pontifex maximus (216), praetor urbanus (215). During his first consulships he did good service against the Ligurians, Gauls and Insubrians. In 212 he defeated Hanno near Beneventum, and with his colleague Appius Claudius Pulcher began the siege of Capua. The capture of this place was considered so important that their imperium was prolonged, but on condition that they should not leave Capua until it had been taken. Hannibal's diversion against Rome interfered with the operations for the moment, but his retirement enabled Flaccus, who had been summoned to Rome to protect the city, to return, and bring the siege to a successful conclusion. He was appointed to the command of the army in Lucania and Bruttium, where he crushed all further attempts at rebellion. Nothing further is known of him. (See PUNIC WARS.)

MARCUS FULVIUS FLACCUS, grandnephew of the foregoing, lived in the times of the Gracchi, of whom he was a strong supporter. After the death of Tiberius Gracchus (133 B.C.) he was appointed in his place one of the commission of three for the distribution of the land. He was suspected of having had a hand in the sudden death of the younger Scipio (129), but there was no direct evidence against him. When consul in 125, he proposed to confer the Roman citizenship on all the allies. This proposal, though for the time successfully opposed by the senate, eventually led to the Social War. The attack made upon the Massilians (who were allies of Rome) by the Salluvii (Salyes) afforded a convenient excuse for sending Flaccus out of Rome. After his return in triumph, he was again sent away (122), this time with Gaius Gracchus to Carthage to found a colony. In 121 he was killed at the same time as Gracchus. Cicero (*Brutus*, 28) speaks of him as an orator of moderate powers, but a diligent student.

See Livy, *Epit.* 59-61; Val. Max. ix. 5. 1; Vell. Pat. ii. 6; Appian, *Bell. Civ.* i. 18, 21, 24-26; Plutarch, *C. Gracchus*, 10. 13; also A. H. J.

Greenidge, *Hist. of Rome* (1904), and authorities quoted under GRACCHUS.

FLACH, GEOFFROI JACQUES (1846-1919), French jurist and historian, was born at Strasbourg. After the war of 1870 he settled in Paris. In 1884 he succeeded Edouard Laboulaye at the Collège de France in the chair of comparative legislation.

His great work, *Les Origines de l'ancienne France*, was produced slowly. Its three volumes—*Le Régime seigneurial* (1886), *Les Origines communales, la féodalité et la chevalerie* (1893) and *La Renaissance de l'état* (1904)—appeared at long intervals, and are not always in complete harmony, but they are marked by originality and vigour. Flach gave them a solid basis by the wide range of his researches, utilizing charters and cartularies (published and unpublished), chronicles, lives of saints and even those dangerous guides, the *chansons de geste*. He pursued the same method in his *L'Origine de l'habitation et des lieux habités en France* (1899), in which he discusses some of the theories circulated by A. Meitzen in Germany and by Arbois de Jubainville in France. Following in the footsteps of the jurist F. C. von Savigny, Flach studied the teaching of law in the middle ages and the Renaissance, and produced *Cujas, les glossateurs et les Bartolistes* (1883), and *Études critiques sur l'histoire du droit romain au moyen âge, avec textes inédits* (1890).

FLACIUS, MATTHIAS (1520-1575), surnamed ILLYRICUS, Lutheran reformer, was born at Albona, in Illyria, on March 3, 1520. He studied under Baptista Egnatius in Venice, and from 1539 onwards at Basel, Tübingen and Wittenberg. Here he was welcomed (1541) by Melanchthon and here he came under the decisive influence of Luther. In 1544 he was appointed professor of Hebrew at Wittenberg. He took his master's degree on Feb. 24, 1546, ranking first among the graduates. He opposed strenuously the "Augsburg Interim," and the compromise of Melanchthon known as the "Leipzig Interim" (see ADIAPHORISTS). Melanchthon wrote of him with venom as a renegade ("alumnus in sinu serpentem"), and Wittenberg became too hot for him. He removed to Magdeburg (Nov. 9, 1551), where his feud with Melanchthon was patched up. On May 17, 1557, he was appointed professor of New Testament theology at Jena; but was soon involved in controversy with Strigel, his colleague, on the synergistic question (relating to the function of the will in conversion). In October 1566 he became pastor of the Lutheran community at Antwerp. In 1567-73 he sought asylum both in Frankfurt and Strasbourg, but in both cases was compelled to leave. Then the prioress, Catharina von Meerfeld, of the convent of White Ladies at Frankfort harboured him and his family in despite of the authorities. He died on March 11, 1575. His son Matthias was professor of philosophy and medicine at Rostock. In spite of his harried life, Flacius was a pioneer of the scientific study of church history, and—if we except, a great exception, the work of Laurentius Valla—of hermeneutics also. There is permanent and continuous value in the principles embodied in Flacius' *Catalogus testium veritatis* (1556; revised edition by J. C. Dietericus, 1672) and his *Clavis scripturae sacrae* (1567), followed by his *Glossa compendiaria in N. Testamentum* (1570).

See J. B. Ritter, *Flacius's Leben u. Tod* (1725); M. Twisten, *M. Flacius Illyricus* (1844); W. Preger, *M. Flacius Illyricus u. seine Zeit* (1859-1861); G. Kawerau, in Herzog-Hauck's *Realencyklopädie* (1899).

FLAG (or "FLAGGE," a common Teutonic word in this sense, but apparently first recorded in English), a piece of bunting or similar material, admitting of various shapes and colours, and waved in the wind from a staff or cord for use in display as a standard, ensign or signal.

Ancient Standards.—Among the remains of the people which has left the earliest traces of civilization, the records of the forms of objects used as ensigns are to be found frequently. From their carvings and paintings, supplemented by ancient writers, it appears that several companies of the Egyptian army had their own particular standards. These were formed of such objects as, there is reason to believe, were associated in the minds of the men with feelings of awe and devotion. Sacred animals, boats, emblems or figures, a tablet bearing a king's name, fan and feather-shaped

symbols, were raised on the end of a staff as standards, and the office of bearing them was looked upon as one of peculiar privilege and great honour. Somewhat similar seem to have been the customs of the Assyrians and Jews. Among the sculptures unearthed at Nineveh, only two different designs have been noticed for standards: one is of a figure drawing a bow and standing on a running bull, the other of two bulls running in opposite directions. We may say these resemble the emblems of war and peace which were attached to the yoke of Darius's chariot. They are borne upon and attached to chariots; and this method of bearing such objects was the custom also of the Persians, and prevailed during the middle ages. That the custom survived to a comparatively modern period is proved from the fact that the "guns," which are the "standards" of the artillery, have from time immemorial been entitled to all the parade honours of the flag, *i.e.*, the symbol of authority. In days comparatively recent there was a "flag gun," usually the heaviest piece, which emblemized authority and served also as the "gun of direction." No representations of Egyptian or Assyrian naval standards have been found, but the sails of ships were embroidered and ornamented with devices, another custom which survived into the middle ages.

In both Egyptian and Assyrian examples, the staff bearing the emblem is frequently ornamented immediately below with flag-like streamers. Rabbinical writers have assigned devices to the Jewish tribes, but their testimony may be doubted. Banners, standards and ensigns are frequently mentioned in the Bible. "Every man of the children of Israel shall pitch by his standard, with the ensign of their father's house" (Num. ii. 2). "Who is she that looketh forth as the morning, fair as the moon, clear as the sun, terrible as an army with banners?" (Cant. vi. 10. *See also* Num. ii. 10, x. 14; Ps. xx. 5, lx. 4; Cant. ii. 4; Is. v. 26, x. 18, lix. 19; Jer. iv. 21.)

The Persians bore an eagle fixed to the end of a lance, and the sun, as their divinity, was also upon their standards, which appear to have been formed of some textile, and were guarded by the bravest men of the army. The Carian soldier who slew Cyrus, the brother of Artaxerxes, was allowed the honour of carrying a golden cock at the head of the army, it being the custom of the Carians to wear that bird as a crest on their helmets. The North American Indians carried poles fledged with feathers from the wings of eagles, and similar customs seem to have prevailed among other semi-savage peoples.

The Greeks bore a piece of armour upon a spear in early times; afterwards the several cities bore sacred emblems or letters chosen for their particular associations—the Athenians the olive and the owl, the Corinthians a pegasus, the Thebans a sphinx, in memory of Oedipus, the Messenians their initial M, and the Lacedaemonians A. A purple dress was placed on the end of a spear as the signal to advance. The Dacians carried a standard representing a contorted serpent, while the dragon was the military sign of many peoples—of the Chinese, Dacians and Parthians among others—and was probably first used by the Romans as the ensign of barbarian auxiliaries.

The question of the *signa militaria* of the Romans is a wide and very important one, having direct bearing on the history of heraldry, and on the origin of national, family and personal devices. With them the custom was reduced to system. "Each century, or at least each manipulus," says Meyrick, "had its proper standard and standard-bearer." In the early days of the republic a handful of hay was borne on a pole, whence probably came the name *manipulus* (Lat. *manus*, a hand). The forms of standards became very various; sometimes a cross piece of wood was placed at the end of a spear and surmounted by the figure of a hand in silver, below round or oval disks, with figures of Mars or Minerva, or in later times portraits of emperors or eminent generals. Figures of animals, such as the wolf, horse, bear and others, were borne; it was not till a still later period that the eagle became the special standard of the legion. According to Pliny, it was Marius who, in his second consulship, ordained that the Roman legions should only have the eagle for their standard; "for before that time the eagle marched foremost with four others—wolves, minotaurs, horses and bears—each

one in its proper order. Not many years passed before the eagle alone began to be advanced in battle, and the rest were left behind in the camp. But Marius rejected them altogether, and since this it is observed that scarcely is there a camp of a legion wintered at any time without having a pair of eagles."

The *vexillum*, the cavalry flag, is described by Livy as a square piece of cloth fastened to a piece of wood fixed crosswise to the end of a spear, somewhat resembling the mediaeval *gonfanon*. These vexilla are to be seen on various Roman coins and medals, on the sculptured columns of Trajan and Antoninus, and on the arch of Titus. The *labarum*, the imperial standard of later emperors, resembled in shape and fixing the vexillum. It was of purple silk richly embroidered with gold, and sometimes was not suspended like the vexillum from a horizontal crossbar, but displayed like our modern flags, *i.e.*, by the attachment of one of its sides to a staff. After Constantine, the labarum bore the monogram of Christ. It is generally supposed that the small scarf, which in mediaeval days was often attached to the pastoral staff or crook of a bishop, was derived from the labarum of the first Christian emperor, Constantine the Great. The Roman standards were guarded with religious veneration in the temples at Rome. It was not unusual for a general to order a standard to be cast into the ranks of the enemy, to add zeal to the onset of his soldiers by exciting them to recover what to them was perhaps the most sacred thing the earth possessed.

Mediaeval Flags.—Although in earlier times drapery was occasionally used for standards, and was often appended as ornament to those of other material, it was probably not until the middle ages that it became their special material.

Early flags were almost purely of a religious character. In Bede's description of the interview between the heathen king Aethelbert and the Roman missionary Augustine, the followers of the latter are said to have borne banners on which silver crosses were displayed. The national banner of England for centuries—the red cross of St. George—was a religious one; in fact the aid of religion seems ever to have been sought to give sanctity to national flags, and the origin of many can be traced to a sacred banner, as is notably the case with the oriflamme of France and the Dannebrog of Denmark. Of the latter the legend runs that King Waldemar of Denmark, leading his troops to battle against the enemy in 1219, saw at a critical moment a cross in the sky. This was at once taken as an answer to his prayers, and an assurance of celestial aid. It was forthwith adopted as the Danish flag and called the "Dannebrog," *i.e.*, the strength of Denmark. Apart from all legend, this flag undoubtedly dates from the 13th century.

The ancient kings of France bore the blue hood of St. Martin upon their standards. The Chape de St. Martin was originally in the keeping of the monks of the abbey of Marmoutier, and the right to take this blue flag into battle with them was claimed by the counts of Anjou. Clovis bore this banner against Alaric in 507, for victory was promised him by a verse of the Psalms which the choir were chanting when his envoy entered the church of St. Martin at Tours; Charlemagne fought under it at the battle of Narbonne. At what precise period the oriflamme, which was originally simply the banner of the abbey of St. Denis, supplanted the Chape de St. Martin as the sacred banner of all France is not known. Probably, however, it gradually became the national flag after the kings of France had transferred the seat of government to Paris, where St. Denis was held in high honour, and the banner hung over the tomb of the saint in the abbey church. The king of France himself was one of the vassals of the abbey of St. Denis for the fief of the Vexin, and it was in his quality of count of Vexin that Louis VI., le Gros, bore this banner from the abbey to battle, in 1124. He is credited with having been the first French king to have taken the banner to war, and it appeared for the last time on the field of fight at Agincourt in 1415. The accounts of its appearance vary considerably. Guillaume Guiart, in his *Chronicle* says:—

Oriflamme est une bannière
De cendal voujoiant et simple
Sans portraiture d'autre affaire

It, therefore, would seem to have been a plain scarlet flag; whilst an English authority states "the celestial auriflamb, so by the French admired, was but of one colour, a square redde banner." The *Chronique de Flandres* describes it as having three points with tassels of green silk attached. The banner of William the Conqueror was sent to him by the pope, and the early English kings fought under the banners of Edward the Confessor and St. Edmund; while the blended crosses of St. George, St. Andrew and St. Patrick still form the national ensign of the united kingdoms of England, Scotland and Ireland.

The Bayeux tapestry, commemorating the Norman conquest of England, contains abundant representations of flags borne upon the lances of the knights of William's army. They appear small in size, and pointed, frequently indented into three points and bearing pales, crosses and roundels. One, a Saxon pennon, is triangular, and roundly indented into four points; one banner is of segmental shape and rayed, and bears the figure of a bird, which has been supposed to represent the raven of the war-flag of the Scandinavian Vikings. The figures are to some extent ornamental and symbolic rather than heraldic; the same insignia do not appear on the shields of the several bearers. The dragon standard which he is known to have borne is placed near Harold; but similar figures appear on the shields of Norman warriors. Standards in form much resembling these dragons appear on the Arch of Titus and the Trajan column as the standards of barbarians.

At the battle of the Standard in 1138 the English standard was formed of the mast of a ship, having a silver pyx at the top and bearing three sacred banners, dedicated severally to St. Peter, St. John of Beverley and St. Wilfrid of Ripon, the whole being fastened to a wheeled vehicle. Representations of three-pointed, cross-bearing pennons are found on seals of as early date as the Norman era, and the warriors in the first crusade bore three-pointed pennons. In 1244 Henry III. gave order for a "dragon to be made in fashion of a standard of red silk sparkling all over with fine gold, the tongue of which should be made to resemble burning fire and appear to be continually moving, and the eyes of sapphires or other suitable stones." *The Siege of Carlaverock*, a poem of the 14th century, describes the heraldic bearings on the banners of the knights at the siege of that fortress. Of the king himself the writer says:—

En sa bannière trois luparte
De or fin estoient mis en rouge;

and he goes on to describe the kingly characteristics these may be supposed to symbolize.

The principal varieties of flags borne during the middle ages were the pennon, the banner and the standard. The "guyd-hommes" or "guidons," "banderolls," "pennoncells," "streamers" or pendants, may be considered as minor varieties. The pennon variety was a purely personal ensign, sometimes pointed, but more generally forked or swallow-tailed at the end. A pennoncell (or penselle) was a small pennon. Flags of this character were largely used on any special occasion of ceremony, and more particularly at State funerals. Amongst the items that ran the total cost of the funeral of Oliver Cromwell up to an enormous sum of money, we find mention of 30 dozen of pennoncells a foot long and costing 20 shillings a dozen, and 20 dozen of the same kind of flags at 12 shillings a dozen.

The banner was, in the earlier days of chivalry, a square flag, though at a later date it is often found greater in length than in depth, as is the case with the national flags of to-day. In many early examples it is found considerably longer in the depth on the staff than in its outward projection from the staff. The banner was charged in a manner exactly similar to the shield of the owner, and it was borne by knights banneret and all above them in rank. In fact flags were originally heraldic emblems, though in modern devices the strict laws of heraldry often have been abandoned.

To create a knight banneret, the king or commander-in-chief in person might tear off the fly of the pennon on the lance of the knight, thus turning it roughly into the square flag or banner,

and so making the knight a banneret. The date at which this dignity originated is uncertain, but it was probably about the period of Edward I. John Chandos is said to have been made a banneret by the Black Prince and the king of Castile at Najara on April 3, 1367. In more modern times Capt. John Smith, who saved the royal banner from the parliamentary troops at Edgehill, is said to have been made a knight banneret by Charles I. From this time the custom of creating knights banneret ceased.

The "gonfalon" or "gonfanon" was a battle flag differing from the ordinary banner in that it was not attached to the pole but hung from it crosswise, and was not always square in shape but serrated, so that the lower edge formed streamers. The gonfalon was in action borne close to the person of the commander-in-chief and denoted his position. In certain of the Italian cities chief magistrates had the privilege of bearing a gonfalon, and for this reason were known as "gonfaloniere."

The standard used was a flag of noble size, long and tapering towards the fly (the "fly" is that portion of the flag farther from the pole, the "hoist" the portion of the flag attached to the pole), the edges of the flag fringed or bordered, and with the ends split and rounded off. The shape was not, however, by any means uniform during the middle ages nor were there any definite rules as to its charges. It varied in size according to the rank of the owner. The standard was, from its size, and as its very name implies, not meant to be carried into action, as was the banner, but to denote the actual position of its possessor on occasions of State ceremonial, or on the tilting ground, and to denote the actual place occupied by him and his following when the hosts were assembled in camp preparatory for battle. It was essentially a flag denoting position, whereas the banner was the rallying point of its followers in the actual field. Its uses are now fulfilled, as far as royalties are concerned, by the "banner" which has now become the "royal standard," and which floats over the palace where the king is in residence, is hoisted at the saluting point when he reviews his troops, and is broken from the mainmast of any ship in his navy the moment that his foot treads its deck. The essential condition of the standard was that it should always have the cross of St. George conspicuous in the innermost part of the hoist immediately contiguous to the staff; the remainder of the flag was then divided fesse-wise by two or more stripes of colours exactly as the heraldic "ordinary" termed "fesse" crosses the shield horizontally. The colours used as stripes, as also those used in the fringe or bordering of the standard, were those which prevailed in the arms of the bearer or were those of his livery. In the time of Henry V. the English royal standard had: colours white and blue, a white antelope standing between two red roses, and in the interspaces more red roses. The motto usually figured on most standards, though occasionally it was missing. An excellent type of the old standard is that of the earls of Percy, which bore the blue lion, the crescent and the fetterlock—all badges of the family—whilst, as tokens of matrimonial alliances with the families of Poynings, Bryan and Fitzpayne, a silver key, a bugle-horn and a falchion were displayed. There was also the historic Percy motto, *Espérance en Dieu*. At Nelson's funeral his banner and standard were borne in the procession, and around his coffin were the banderolls—square, bannerlike flags bearing the various arms of his family lineage. Nelson's standard bore his motto, *Palmarum qui meruit ferat*, but, in lieu of the cross of St. George, it bore the union of the crosses of St. George, St. Andrew and St. Patrick, the mediaeval England having expanded into the United Kingdom of Great Britain and Ireland. Again, at the funeral of the duke of Wellington we find amongst the flags his personal banner and standard, and ten banderolls of the duke's pedigree and descent.

The guidon, a name derived from the Fr. *Guyd-homme*, was somewhat similar to the standard, but without the cross of St. George, rounded at the end, less elongated and altogether less ornate. It was borne by a leader of horse, and according to one writer "must be two and a half yards or three yards long, and therein shall no armes be put, but only the man's crest, cognisance, and devyce."

The streamer, so called in Tudor days but now better known as the pennant or pendant, was a long, tapering flag; which it was directed "shall stand in the top of a ship or in the fore-castle, and therein be put no armes, but the man's cognisance or devyce, and may be of length 20, 30, 40 or 60 yards, and is slitt as well as a guidon or standard." Amongst the fittings of the ship that took Beauchamp, earl of Warwick, to France in the reign of Henry VII. was a "grete stremour for the shippe xl yarges in length viij yarges in brede." In the hoist was "a grete bere holding a raggid staffe," and the rest of the fly "powdrid full of raggid staves."

NATIONAL FLAGS

British.—The royal standard of Great Britain now bears the arms of England quartered with those of Scotland and Ireland. From the time of Richard I. it had borne the arms of England only, until Edward III. began to set the old arms of France in the first and fourth quarters with those of England in the second and third. Following the custom of the French king, Henry V. reduced the number of his *fleurs-de-lis* to three. The next change was made when James I. had the first and fourth quarters of France quartered with England, the second quarter of Scotland and the third of Ireland. William III. set over all this an escutcheon of Nassau, Queen Anne's first and fourth quarters were of England parted with Scotland, the second quarter of France, the third of Ireland. George I. showed the same, changing the fourth quarter for the arms of the electors of Hanover. In 1801 the arms of the royal banner or standard were as they are now, save for Hanoverian arms on an escutcheon in the middle, which was removed at the accession of Queen Victoria. It is worthy of note, however, that in the royal standard of King Edward VII. which hangs in the chapel of St. George at Windsor, the ordinary "winged woman" form of the harp in the Irish third quartering is altered to a harp of the old Irish pattern.

Up to the time of the Stuarts it had been the custom of the lord high admiral or person in command of the fleet to fly the royal standard as deputy of the sovereign. When royalty ceased to be, a new flag was devised by the council of State for the Commonwealth, which comprised the "arms of England and Ireland in two several escutcheons in a red flag within a compartment." In other words, it was a red flag containing two shields, the one bearing the cross of St. George, red on a white ground, the other the harp, gold on a blue ground, and round the shields was a wreath of palm and shamrock leaves. One of these flags is still in existence at Chatham dockyard, where it is kept in a wooden chest which was taken out of a Spanish galleon at Vigo by Admiral Sir George Rooke in 1704. When Cromwell became Protector of the Commonwealth of England, Scotland and Ireland, he devised for himself a personal standard. This had the cross of St. George in the first and fourth quarters, the cross of St. Andrew, a white saltire on a blue ground, in the second, and the Irish harp in the third. His own arms—a lion on a black shield—were imposed on the centre of the flag. No one but royalty has a right to fly the royal standard, and though it is constantly seen flying for purposes of decoration its use is irregular. There has, however, always been one exception, namely that the lord high admiral when in executive command of a fleet has always been entitled to fly the royal standard. For example, Lord Howard flew it from the mainmast of the "Ark Royal" when he defeated the Spanish Armada; the duke of Buckingham flew it as lord high admiral in the reign of Charles I., and the duke of York fought under it when he commanded during the Dutch Wars.

The national flag of the British empire is the Union Jack in which are combined in union the crosses of St. George, St. Andrew and St. Patrick. St. George had long been a patron saint of England, and his banner of silver with a cross gules its national ensign. St. Andrew in the same way was the patron saint of Scotland, and his banner of azure with a saltire silver the national ensign of Scotland. On the union of the two crowns James I. issued a proclamation ordaining that "henceforth all our subjects of this Isle and Kingdom of Greater Britain and the members thereof, shall bear in their main-top the red cross

commonly called St. George's cross, and the white cross commonly called St. Andrew's cross, joined together according to a form made by our heralds, and sent by us to our admiral to be published to our said subjects; and in their fore-top our subjects of south Britain shall wear the red cross only, as they were wont and our subjects of north Britain in their fore-top, the white cross only as they were accustomed." This was the first Union Jack, as it is generally termed, though strictly the name of the flag is the "Great Union," and it is only a "Jack" when flown on the jackstaff of a ship of war. At the death of Charles I., the union with Scotland being dissolved, the ships of the parliament reverted to the simple cross of St. George, but the union flag was restored when Cromwell became protector, with the Irish harp imposed upon its centre. On the Restoration, Charles II. removed the harp and so the original union flag was restored, and continued as described until the year 1801, when, on the legislative union with Ireland, a cross styled like that of St. Patrick, a saltire gules, in a field silver, was incorporated in the union flag. So to combine these three crosses without losing the distinctive features of each was not easy; each cross must be distinct, and retain equally distinct its fimbriation, or bordering, which denotes the original ground. In the first union flag, the red cross of St. George with the white fimbriation that represented the original white field was simply imposed upon the white saltire of St. Andrew with its blue field. To place the red saltire of St. Patrick on the white saltire of St. Andrew would have been to obliterate the latter, nor would the red saltire have its proper bordering denoting its original white field; even were the red saltire narrowed in width the portion of the white saltire that would appear would not be the St. Andrew saltire, but only the fimbriation appertaining to the saltire of St. Patrick. The difficulty has been got over by making the white broader on one side of the red than the other. In fact, the continuity of direction of the arms of the St. Patrick red saltire has been broken by its portions being removed from the centre of the oblique points that form the St. Andrew's saltire. Thus both the Irish and Scottish saltires can be distinguished easily from one another, whilst the red saltire has its due white fimbriation.

The Union Jack is the most important of all British ensigns, and is flown by representatives of the empire all the world over. It flies from the jackstaff of every man-of-war in the navy. When flown by the governor-general of India the star and device of the order of the Star of India are borne in the centre. Colonial governors fly it with the badge of their colony displayed in the centre. Diplomatic representatives use it with the royal arms in the centre. As a military flag, it is flown over fortresses and headquarters, and on all occasions of military ceremonial. Hoisted at the mainmast of a man-of-war it is the flag of an admiral of the fleet.

Military flags in the shape of regimental standards and colours, and flags used for signalling, are described elsewhere, and it will here be only necessary to deal with the navy and admiralty flags.

The origin of the three ensigns—the red, white and blue—had its genesis in the navy. In the days of huge fleets, such as prevailed in the Tudor and Stuart navies, there were, besides the admiral in supreme command, a vice-admiral as second in command, and a rear-admiral as third in command, each controlling his own particular group or squadron. These were designated centre, van, and rear, the centre almost invariably being commanded by the admiral, the vice-admiral taking the van and the rear-admiral the rear squadron. In order that any vessel in any group could distinguish its own admiral's ship, the flagships of centre, van, and rear flew respectively a plain red, white, or blue flag, and so came into being those naval ranks of admiral, vice-admiral and rear-admiral of the red, white and blue which continued down to as late as 1864. As the admiral in supreme command flew the union at the main, there was no rank of admiral of the red, and it was not until Nov. 1805 that the rank of admiral of the red was added to the navy as a special compliment to reward Trafalgar. About 1652, so that each individual ship in the squadron should be distinguishable as well as the flagships, each vessel carried a large red,

white or blue flag according as to whether she belonged to the centre, van, or rear, each flag having in the left-hand upper corner a canton, as it is termed, of white bearing the St. George's cross. These flags were called ensigns, and it is, of course, due to the fact that the union with Scotland was for the time dissolved that they bore only the St. George's cross. Even when the restoration of the Stuarts restored the *status quo* the cross of St. George still remained alone on the ensign, and it was not altered until 1707 when the bill for the Union of England and Scotland passed the English parliament. In 1801, when Ireland joined the Union, the flag, of course, became as we know it to-day. All these three ensigns belonged to the royal navy, and continued to do so until 1864, but as far back as 1707 ships of the mercantile marine were instructed to fly the red ensign. As ironclads replaced the wooden vessels and fleets became smaller the inconvenience of three naval ensigns was manifest, and in 1864 the grades of flag officer were reduced again to admiral, vice-admiral, and rear-admiral, and the navy abandoned the use of the red and blue ensigns, retaining only the white ensign as its distinctive flag. The mercantile marine retained the red ensign which they were already using, whilst the blue ensign was allotted to vessels employed on the public service whether home or colonial.

The white ensign is therefore essentially the flag of the royal navy. It should not be flown anywhere or on any occasion except by a ship (or shore establishment) of the royal navy, with but one exception. By a grant of William IV. dating from 1829 vessels belonging to the Royal Yacht Squadron, the chief of all yacht clubs, are allowed to fly the white ensign. From 1821 to 1829 ships of the squadron flew the red ensign, as that of highest dignity, but as it was also used by merchant ships, they then obtained the grant of the white ensign as being more distinctive. Some few other yacht clubs flew it until 1842, when the privilege was withdrawn by an admiralty minute. By some oversight the order was not conveyed to the Royal Western of Ireland, whose ships flew the white ensign until in 1857 the usage was stopped. Since that date the Royal Yacht Squadron alone has had the privilege. Any vessel of any sort flying the white ensign, or pennant, of the navy is committing a grave offence, and the ship can be boarded by any officer of His Majesty's service, the colours seized, the vessel reported to the authorities, and a penalty inflicted on the owners or captain or both. The penalty incurred is £500 fine for each offence, as laid down in the 73rd section of the Merchant Shipping Act, 1894.

Besides the white ensign the ship of war flies a long streamer from the maintopgallant masthead. This, which is called a pennant, is flown only by ships in commission; it is, in fact, the sign of command, and is first hoisted when a captain commissions his ship. The pennant, which was really the old "pennoncell," was of three colours for the whole of its length, and towards the end left separate in two or three tails, and so continued till the end of the great wars in 1816. Now, however, the pennant is a long white streamer with the St. George's cross in the inner portion close to the mast. Pennants have been carried by men-of-war from the earliest times, prior to 1653 at the yard-arm, but since that date at the maintopgallant masthead.

The blue ensign is exclusively the flag of the public service other than the royal navy, and is as well the flag of the royal naval reserve. It is flown also by certain authorized vessels of the British mercantile marine, the conditions governing this privilege being that the captain and a certain specified portion of the officers and crew shall belong to the ranks of the royal naval reserve. When flown by ships belonging to British Government offices the seal or badge of the office is displayed in the fly. For example, hired transports fly it with the yellow anchor in the fly; the marine department of the Board of Trade has in the fly the device of a ship under sail; the telegraph branch of the post-office shows in the fly a device representing Father Time with his hour-glass shattered by lightning; the ordnance department displays upon the fly a shield with a cannon and cannon balls upon it. Certain yacht clubs are also authorized by special admiralty warrant to fly the blue ensign. Some of these display it plain; others show in the fly the distinctive badge of the club.

Consuls-general, consuls and consular agents also have a right to fly the blue ensign, the distinguishing badge in their case being the royal arms.

The red ensign is the distinguishing flag of the British merchant service, and special orders to this effect were issued by Queen Anne in 1707, and again by Queen Victoria in 1864. The order of Queen Anne directed that merchant vessels should fly a red flag "with a Union Jack described in a canton at the upper corner thereof next the staff," and this is probably the first time that the term "Union Jack" was officially used. In some cases those yacht clubs which fly the red ensign change it slightly from that flown by the merchant service, for they are allowed to display the badge of the club in the fly. Colonial merchantmen usually display the ordinary red ensign, but, provided they have a warrant of authorization from the admiralty, they can use the ensign with the badge of the colony in the fly.

There are two other British sea flags which are worthy of brief notice. These are the admiralty flag and the flag of the master of Trinity House. The Admiralty flag is a plain red flag with a clear anchor in the centre in yellow. In a sense it is a national flag, for the sovereign hoists it when afloat in conjunction with the royal standard and the Union Jack. It would appear to have been first used by the duke of York as lord high admiral, who flew it when the sovereign was afloat and had the royal standard flying in another ship. When a board of commissioners was appointed to execute the office of lord high admiral this was the flag adopted, and in 1691 we find the admiralty, minuting the navy board, then a subordinate department, "requiring and directing it to cause a fitting red silk flag, with the anchor and cable therein, to be provided against Tuesday morning next, for the barge belonging to this board." In 1725, presumably as being more artistic, the cable in the device was twisted round the stock of the anchor. It was thus made into a "foul anchor," the thing of all others that a sailor most hates, and this despite the fact that the first lord at the time, the earl of Berkeley, was himself a sailor. The anchor retained its unseamanlike appearance, and was not "cleared" till 1815, and even to this day the buttons of the naval uniform bear a "foul anchor." The "anchor" flag is solely the emblem of an administrative board; it does not carry the executive or combatant functions which are vested in the royal standard, the union or an admiral's flag, but on two occasions it has been made use of as an executive flag. In 1719 the earl of Berkeley, who at the time was not only first lord of the admiralty, but vice-admiral of England, obtained the special permission of George I. to hoist it at the main instead of the union flag. Again in 1869, when Childers, then first lord, accompanied by some members of his board, went on board the "Agincourt" he hoisted the Admiralty flag and took command of the combined Mediterranean and Channel Squadrons, thus superseding the flags of the two distinguished officers who at the time were in command of these squadrons. It is hardly necessary to add that throughout the navy there was a very distinct feeling of dissatisfaction at the innovation. When the Admiralty flag is flown by the sovereign it is hoisted at the fore, his own standard being of course at the main, and the union at the mizzen.

The flag of the master of the Trinity House is the red cross of St. George on its white ground, but with an ancient ship on the waves in each quarter; in the centre is a shield with a precisely similar device and surmounted by a lion.

The sign of a British admiral's command afloat is always the same. It is the St. George's cross. Of old it was borne on the main, the fore, or the mizzen, according as to whether the officer to whom it pertained was admiral, vice-admiral, or rear-admiral, but, as ironclads superseded wooden ships, and a single pole mast took the place of the old three masts, a different method of indicating rank was necessitated. To-day the flag of an admiral is a square one, the plain St. George's cross. When flown by a vice-admiral it bears a red ball on the white ground in the upper canton next to the staff; if flown by a rear-admiral there is a red ball in both the upper and lower cantons. As nowadays most battleships have two masts, the admiral's flag is hoisted at the one which has no masthead semaphore. The admiral's flag is always a square one,

but that of a commodore is a broad white pennant with the St. George's cross. If the commodore be first class the flag is plain; if of the second class the flag has a red ball in the upper canton next to the staff. The same system of differentiating rank prevails in most navies, though very often a star takes the place of the ball. In some cases the indications of rank are differently shown. For instance, in the Japanese navy the distinction is made by a line of colour on the upper or lower edges of the flag.

The flags of the British colonies are the same as those of the mother country, but differentiated by the badge of the colony being placed in the centre of the flag if it is the Union Jack, or in the fly if it be the blue or red ensign. Examples of these are shown in the Plate, where over the red ensigns illustrated is that of New Zealand, the device of the colony being the southern cross in the fly. The same flag, with a large six-pointed star, emblematic of the six States immediately under the union and an additional small star in the device of the Southern Cross, forms the merchant flag of the federated Commonwealth of Australia. The government flag shown is precisely the same as the merchant flag except that the device is placed on the blue instead of the red ensign. Another red ensign shown is that of the Dominion of Canada, the device in the fly being the armorial bearings of the Dominion. As the viceroy of India, as representative of the King-Emperor, flies the Union Jack with the badge of the Order of the Star of India in the centre, so the Dominion or colonial governors or high commissioners (except in the case of the Irish Free State) fly the Union Jack with the arms of the Dominion or colony they preside over on a white shield in the centre and surrounded by a laurel wreath. In the case of Canada the wreath, however, is not of laurel but of maple, which is the special emblem of the Dominion.

American.—Before the Declaration of Independence the flags of those colonies which now form the United States of America were very various. In the early days of New England the Puritans objected to the red cross of St. George, not from any disloyalty to the mother country, but from a conscientious objection to what they deemed an idolatrous symbol. By the year 1700 most of the colonies had devised badges to distinguish their vessels from those of England and of each other. In the early stages of the revolutionary war each State adopted a flag of its own; thus, that of Massachusetts bore a pine tree, South Carolina displayed a rattlesnake, New York had a white flag with a black beaver, and Rhode Island a white flag with a blue anchor upon it. Even after the Declaration of Independence, and the introduction of the stars and stripes, the latter underwent many changes in the manner of their arrangement before taking the position at present established. In 1775 a committee was appointed to consider the question of a single flag for the 13 States. It recommended that the Union Jack be retained in the upper corner next to the staff, the remainder of the field of the flag to be of 13 horizontally disposed stripes alternately red and white. This flag, known as the Grand Union or Cambridge flag, was first displayed when Washington first took command of the army at Cambridge. It was raised on December 3, 1775 on the "Alfred," flagship of the new American navy, by the senior lieutenant of the ship, John Paul Jones. When the Declaration of Independence was signed in Philadelphia in 1776 the new nation would not use the Union Jack in their flag. So on June 14, 1777, congress resolved "that the flag of the United States be 13 stripes, alternate red and white; that the union be 13 stars, white on a blue field, representing a constellation." The first American unfurling of the Stars and Stripes over a warship was by John Paul Jones when he took command of the "Ranger" in June, 1777. It was first carried into battle at the battle of Brandywine in September, 1777. This was the origin of the national flag, but at first, as the number of the stripes were unequal, the flag very often varied, sometimes having seven white and six red stripes, and at other times seven red and six white, and it was not for some considerable time that it was authoritatively laid down that the latter arrangement was the one to be adopted. It has also been held that the stars and stripes of the American national flag, as well as the eagle, were suggested by the crest and arms of the Washington family. The latter supposition is absurd, for the Washington crest was a raven. The

Washington arms were a white shield having two horizontal red bars, and above these a row of three red "molets." This might, by a stretch of imagination, be supposed to have inspired the original idea of the flag which was that each State in the Union should be represented in the national flag by a star and stripe. Naturally other States coming into the Union expected the same privilege. After Vermont in 1790 and Kentucky in 1792 had entered the Union, the stars and stripes were changed in number from 13 to 15. Later on other States joined, and in the year 1818 it was determined to go back to the original 13 stripes, but to place a star for each State in the blue union canton in the top corner of the flag next the staff. By the admission of Arizona as a State in 1912 the number of stars became 48, arranged in six horizontal rows of eight stars each. Thus the stars show the exact number of States in the Union, whilst the stripes denote the original number of the States that formed the union. The flag of the president of the United States is an eagle on a blue field, bearing on its breast a shield displaying stripes, and above, the national motto *E pluribus unum*, and, above, a design of the 13 stars.

French.—To come to flags of other countries, nowhere have historical events caused so much change in the standards and national ensigns of a country as in the case of France. The oriflamme and the Chape de St. Martin were succeeded at the end of the 16th century, when Henry III., the last of the house of Valois, came to the throne, by the white standard powdered with *fleurs-de-lis*. This in turn gave place to the famous tricolour. The tricolour was introduced at the time of the Revolution, but the origin of this flag and its colours is a disputed question. Some maintain that the intention was to combine in the flag the blue of the Chape de St. Martin, the red of the oriflamme, and the white flag of the Bourbons. By others the colours are said to be those of the city of Paris. The tricolour is divided vertically into three parts of equal width—blue, white and red, the red forming the fly, the white the middle, and the blue the hoist of the flag. During the first and second empires the tricolour became the imperial standard, but in the centre of the white stripe was placed the eagle, whilst all three stripes were richly powdered over with the golden bees of the Napoleons. The tricolour is now the sole flag of France.

Other Countries.—The most general and a few of the newest of the various national flags are figured in the Plate. Representing Great Britain are shown the royal standard and Union Jack (the national flag). The next line shows 4 other flags of Great Britain: the white ensign of the royal navy, the blue ensign of Government service, and two red ensigns of the commercial marine, colonial flags being shown in the case of the three latter ensigns. The two Japanese flags shown are the man-of-war ensign—a rising sun, generally known as the sunburst—and the flag of the mercantile marine, in which the red ball is used without the rays and placed in the centre of the white field. The imperial standard of Japan is a golden chrysanthemum on a red field. It is essential that the chrysanthemum should invariably have 16 petals. Heraldry in Japan is of a simpler character than that of Europe, and is practically limited to the employment of *Mon*. The great families of Japan possess at least one, and in many cases even three, *Mon*. The imperial family use two, the one *Kiku no go Mon* (the august chrysanthemum badge) and *Kiri no go Mon* (the august Kiri badge).

The German imperial standard had the iron cross with its white border displayed on a yellow field, diapered over in each of the four quarters with three black eagles and a crown. In the centre of the cross was a shield bearing the arms of Prussia surmounted by a crown, and surrounded by a collar of the Order of the Black Eagle. In the four arms of the crown was the legend *Gott mit uns* 1870. The national flag of the German republican *Reich* is now a tricolour of three horizontal stripes—black, red and yellow. The United States flag and the tricolour of France have already been fully dealt with, and in both countries the one flag is common to both men-of-war and ships of the mercantile marine.

Austria's national flag now has three horizontal stripes. Red above, white in the centre and red below.

The green, white and red Italian tricolour was adopted in 1805, when Napoleon I. formed Italy into one kingdom. It was adopted again in 1848 by the Nationalists of the peninsula, accepted by the king of Sardinia, and, charged by him with the arms of Savoy, it became the flag of a united Italy. The man-of-war flag is precisely similar to that of the mercantile marine, except that in the case of the former the shield of Savoy is surmounted by a crown. The royal standard is a blue flag. In the centre is a black eagle crowned and displaying on its breast the arms of Savoy, the whole surrounded by the collar of the Most Sacred Annunziata, the third in rank of all European orders. In each corner of the flag is the royal crown.

For the Portuguese republic the flag is one of the few national flags that are parti-coloured. It is part green, part red, with, in the centre, the arms of Portugal.

In the Spanish ensigns red and yellow are the prevailing colours, and here again the arrangement differs from that generally used. The navy flag has a yellow central stripe, with red above and below. To be correct the yellow should be half the width of the flag, and each of the red stripes a quarter of the width of the flag. The central yellow stripe is charged in the hoist with an escutcheon containing the arms of Castile and Leon, and surmounted by the royal crown. In the mercantile flag the yellow centre is without the escutcheon, and is one-third of the entire depth of the flag, the remaining thirds being divided into equal stripes of red and yellow, the yellow above in the upper part of the flag, the red in the lower.

The flag of the Soviet Government in Russia (1929) is the red flag charged, in the upper quarter of the hoist, with a golden sickle crossed saltirewise with a golden hammer, a star (molet) above.

The flag of the Russian mercantile marine was a horizontal tricolour of white, blue and red. Originally, it was a tricolour of blue, white and red, and it is said that the idea of its colouring was taken by Peter the Great when learning shipbuilding in Holland, for as the flag then stood it was simply the Dutch ensign reversed. Later, to make it more distinctive, the blue and white stripes changed places. The flag of the Russian navy was the blue saltire of St. Andrew on a white ground. The imperial standard was of a character akin to that of Austria; the ground was yellow, the centre bearing the imperial double-headed eagle, a badge that dates back to 1472, when Ivan the Great married a niece of Constantine Palaeologus and assumed the arms of the Greek empire. On the breast of the eagle was an escutcheon charged with the emblem of St. George and the Dragon on a red ground, and this was surrounded by the collar of the order of St. Andrew. On the splayed wings of the eagle were small shields bearing the arms of the various provinces of the empire.

The Rumanian flag is a blue, yellow and red tricolour, the stripes vertical, with the blue stripe forming the fly. Yugoslavia, the new kingdom of the Serbs, Croats and Slovenes has a horizontal tricolour, the top stripe blue, the middle white and the lower red. The Bulgarian flag is a similar tricolour, white, green and red, the white stripe uppermost.

The flags of all the three Scandinavian kingdoms are somewhat similar in design. That of Denmark, the Dannebrog, has been already alluded to, and it is shown in our illustration as flown by the Danish navy. The mercantile marine flag is precisely similar, but rectangular instead of being swallow-tailed. The Swedish flag is a yellow cross on a blue ground. When flown from a man-of-war it is forked as in the Danish, but the longer arm of the cross is not cut off but pointed, thus making it a three-pointed flag as illustrated. For the mercantile marine the flag is rectangular. When Norway separated from Denmark in 1814, the first flag was red with a white cross on it, and the arms of Norway in the upper corner of the hoist, but as this was found to resemble too closely the Danish flag, a blue cross with a white border was substituted for the white cross. This, it will be seen, is the Danish flag with a blue cross imposed upon the white one. For a man-of-war the flag is precisely similar to that of Sweden in shape; *i.e.*, converted from the rectangular into the three-pointed design. While Sweden and Norway remained united the flag of each

remained distinct, but each bore in the top canton of the hoist a union device, being the combination of the Norwegian and Swedish national colours and crosses. In each of the three above nationalities the flag used for a royal standard is the man-of-war flag with the royal arms imposed on the centre of the cross.

The Belgian tricolour is vertical, the stripes being black next the hoist, yellow in the centre and red in the fly. That of the Netherlands is a horizontal tricolour, red above, white in the centre and blue below. In both countries the same flag is common to both navy and mercantile marine, but when the flag is used as a royal standard the royal arms are displayed in the central stripe. The black, yellow and red of the Belgian flag are the colours of the duchy of Brabant, and were adopted in 1831 when the monarchy was founded. The original Dutch colours adopted when Holland declared its independence were orange, white and blue, the colours of the house of Orange, and when and how the orange became red is not quite clear, though it was certainly prior to 1643.

The blue and white which form the colouring of the Greek flag shown in our illustration were adopted by the National Assembly at Epidaurus on Jan. 7, 1822. They also happen to be the colours of the house of Bavaria, a member of which, Prince Otho, was elected to the throne of Greece in 1832. The stripes are nine in number—five blue and four white—with, in the upper corner of the hoist, a canton bearing a white cross on a blue ground.

The very simple flag of Switzerland is one of great antiquity, for it was the emblem of the nation as far back as 1339, and probably considerably earlier. In addition to the national flag of the Swiss confederation, each canton has its own cantonal colours. In each case the flag has its stripes disposed horizontally. Basel, for instance, is half black, half white; Berne, half black, half red; Glarus, red, black and white.

The Turkish crescent moon and star were the device adopted by Mohammed II. when he captured Constantinople in 1453. Originally they were the symbol of Diana, the patroness of Byzantium, and were adopted by the Ottomans as a triumph, for they had always been the special emblem of Constantinople, and even now in Moscow and elsewhere the crescent emblem and the cross may be seen combined in Russian churches, the crescent badge, of course, indicating the Byzantine origin of the Russian church. The symbol originated at the time of the siege of Constantinople by Philip the father of Alexander the Great, when a night attempt of the besiegers to undermine the walls was betrayed by the light of a crescent moon, and in acknowledgment of their escape the Byzantines raised a statue to Diana, and made her badge the symbol of the city. Both the man-of-war and mercantile marine flags are the same, but the imperial standard of the sultan was scarlet, and bore in its centre the device of the reigning sovereign. This device was known as the "Tughra," and consisted of the name of the sultan, the title of khan, and the epithet *al-Muzaffar Daima*, which means "the ever victorious." The origin of the "Tughra" was that the sultan Murad I., who was not of scholarly parts, signed a treaty by wetting his open hand with ink, and pressing it on the paper, the first, second and third fingers making smears close together, the thumb and fourth finger leaving marks apart. Within the marks thus made the scribes wrote in the name of Murad, his title, and the epithet above quoted. The "Tughra" dated from the latter part of the 14th century.

The imperial flag of Persia is a horizontal tricolour of green, white and red, with the lion and sun on the white ground. The merchant flag is somewhat similar, but omits the lion and sun device.

The national flag of Siam has five horizontal stripes of red, white, blue, white and red. The naval flag is similar but has the addition of a red ball in the middle within which is a white elephant. That of Korea, a white flag with, in the centre, a ball, half red, half blue, the colours being curiously intermixed, the whole being precisely as if two large commas of equal size, one red and the other blue, were united to form a complete circle.

The Chinese republic flies a flag of red with a blue field in the upper hoist bearing a white ball surrounded by 16 triangular rays.

Among the South American republics the Brazilian flag is peculiar inasmuch as it is the only national flag which carries a motto.

Mexico flies precisely the same tricolour as Italy, but plain in the case of the merchant ensign, and charged on the central stripe with the Mexican arms when flown as a man-of-war ensign.

The Argentine flag is flown by the navy, but, when used by the mercantile marine, the sun emblazoned on the central white stripe is omitted, the flag otherwise being precisely the same.

The Venezuelan flag of the navy is also the flag of the mercantile marine, but the shield bearing the arms of the State is not introduced into the yellow top stripe in the corner near the hoist, as in the naval flag.

The Chilean ensign is used alike by men-of-war and vessels in the mercantile marine, but, when flown as the standard of the president, the Chilean arms and supporters are placed in the centre of the flag.

The flag of the mercantile marine of Peru is plain red, white, red in vertical stripes, and becomes the naval ensign when charged on the central stripe with the Peruvian arms as shown in our illustration. In fact, in nearly every case with the South American republics, the ordinary mercantile marine flag becomes that of the war navy by the addition of the national arms, and in some cases is used in the same way as a presidential flag.

In nearly every case the flags of the lesser American republics are tricolours, and in a very great many of them the flags are by no means such combinations as would meet with the approval of European heralds. All flag devising should be in accordance with heraldic laws, and one of the most important of these is that colour should not be placed on colour, nor metal on metal, yellow in blazonry being the equivalent of gold and white of silver. Hence, properly devised tricolours are such as, for example, those of France, where the red and blue are divided by white, or Belgium, where the black and red are divided by yellow. On the other hand, the yellow, blue, red of Venezuela is heraldically an abomination.

Manufacture and Miscellaneous Uses.—Flags, the manufacture of which is quite a large industry, are almost invariably made from bunting, a very light, tough and durable woollen material. The regulation bunting used in the British navy is in gin. widths, and the flag classes in size according to the number of breadths of bunting of which it is composed. The great centre of the manufacture of flags, as far as the British navy is concerned, is the dockyard at Chatham. Ensigns and Jacks are made in different sizes; the largest ensign made is 33ft. long by 16½ft. in width; the largest Jack issued is 24ft. long and 12ft. wide.

The dimensions of a flag should be either square or in the proportion of two to one, and it is this latter dimension that is used in the British navy and generally.

Signalling flags are dealt with elsewhere (*see* SIGNAL), and here it will only be necessary to make brief allusion to some international customs with regard to the use of flags to indicate certain purposes. For long a blood-red flag has always been used as a symbol of mutiny or of revolution. The black flag was in days gone by the symbol of the pirate; to-day, in the only case in which it survives, it is flown after an execution to indicate that the requirements of the law have been duly carried out. All over the world a yellow flag is the signal of infectious illness. A ship hoists it to denote that there are some on board suffering from yellow fever, cholera or some such infectious malady, and it remains hoisted until she has received quarantine. This flag is also hoisted on quarantine stations. The white flag is universally used as a flag of truce.

At sea striking of the flag denotes surrender. When the flag of one country is placed over that of another the victory of the former is denoted, hence in time of peace it would be an insult to hoist the flag of one friendly nation above that of another. If such were done by mistake, say in "dressing ship" for instance, an apology would have to be made. This custom of hoisting the flag of the vanquished beneath that of the victor is of comparatively modern date, as up to about a century ago the sign of victory was to trail the enemy's flag over the taffrail in the water.

Each national flag must be flown from its own flagstaff, and this is often seen when the allied forces of two or more powers are in joint occupation of a town or territory. To denote honour and respect a flag is "dipped." Ships at sea salute each other by "dipping" the flag, *i.e.*, by running it slowly down from the masthead, and then smartly replacing it. When troops parade before the sovereign the regimental flags are lowered as they salute him. A flag flying half-mast high is the universal symbol of mourning. When a ship has to make the signal of distress, this is done by hoisting the national ensign reversed, *i.e.*, upside down. If it is wished to accentuate the imminence of the danger it is done by making the flag into a "weft," *i.e.*, by knotting it in the middle. This means of showing distress at sea is of very ancient usage, for in naval works written as far back as the reign of James I. we find the "weft" mentioned as a method used by ships for showing distress.

We have already alluded to the Union Jack as used for denoting nationality, and as a flag of command, but it also serves many other purposes. For instance, if a court-martial is being held on board any ship the Union Jack is displayed while the court is sitting, its hoisting being accompanied by the firing of a gun. In a fleet in company the ship that has the guard for the day flies it. With a white border it forms the signal for a pilot, and in this case is known as a Pilot Jack. In all combinations of signalling flags which denote a ship's name the Union Jack forms a unit. Lastly, it figures as the pall of every sailor or soldier of the empire who receives naval or military honours at his funeral.

Bland, *National Banners: Their History and Construction* (1892) (one of a series of Heraldic Tracts, 1850–92, Br. Museum Library, No. 9906, b. 9; this pamphlet gives the design of the national banners of St. George, St. Andrew and St. Patrick, and illustrates and tells the story of the composition of the three flags into the great union flag, commonly known as the Union Jack); S. Eardley-Wilmot, *Our Flags: Their Origin, Use and Traditions* (1901), an excellent treatise, historical and narrative, on all flags of the British empire; G. H. Preble, *A History of the Flag of the United States* (Boston, 1872); E. Hulme, *Flags of the World: Their History, Blazonry and Associations* (1897), a most complete monograph on the subject, illustrated with a very complete series of plates; *Admiralty Book of Flags of all Nations*, printed for H.M. Stationery office, 1889, kept up to date by the publication periodically of *Errata*, officially issued under an admiralty covering letter; *Flags of the United States and Other Countries*, published by the Hydrographic office of the navy, printed by authority (Washington, 1928). The last two works have no letterpress beyond titles, but contain, to scale, delineations of all the flags at present used officially by all nations. Between the two there are no discrepancies, and the delineation of a flag taken from either may be assumed as absolutely correct. Both are respectively the guides for flag construction in the British navy and the United States navy. (H. L. S.)

FLAGELLANTS, in religion, the name given to those who scourge themselves, or are scourged, by way of discipline or penance (*Lat. flagellare*, to whip). Voluntary flagellation, as a form of exalted devotion, occurs in almost all religions. According to Herodotus, it was the custom of the ancient Egyptians to beat themselves during the annual festival in honour of Isis. In Sparta children were flogged before the altar of Artemis Orthia till the blood flowed. At Alea, in the Peloponnese, women were flogged in the temple of Dionysus. In the Christian church flagellation was originally a punishment, and was practised not only by parents and schoolmasters, but also by bishops, who thus corrected offending priests and monks. Gradually, however, voluntary flagellation appeared in the *libri poenitentiales* as a very efficacious means of penance. In the 11th century this new form of devotion was extolled by some of the most ardent reformers in the monastic houses of the west. The early Franciscans flagellated themselves with characteristic rigour, and it is no matter of surprise to find the Franciscan, St. Anthony of Padua, preaching the praises of this means of penance. But the flagellant fraternities were the result of spontaneous popular movements, the real sources of which are not easily analysed. About 1259 these fraternities were distributed over the greater part of northern Italy. The contagion spread very rapidly, extending as far as the Rhine provinces, and, across Germany, into Bohemia. Day

and night, long processions of all classes and ages, headed by priests carrying crosses and banners, perambulated the streets in double file, reciting prayers and drawing the blood from their bodies with leathern thongs. The magistrates in some of the Italian towns expelled the flagellants with threats, and for a time the sect disappeared. The disorders of the 14th century, however, the numerous earthquakes, and the Black Death, which had spread over the greater part of Europe, produced a condition of ferment and mystic fever which was very favourable to a recrudescence of morbid forms of devotion. The flagellants reappeared from eastern Europe, and, in spite of discouragement, spread to the Rhine, and penetrated as far as Holland and Flanders. A band of 100 marched from Basle to Avignon to the court of Pope Clement VI. who saw in the movement a menace to the priesthood, and in October 1349 published a bull commanding the bishops and inquisitors to stamp out the growing heresy. In pursuance of the pope's orders numbers of the sectaries perished at the stake or in the cells of the inquisitors and the episcopal justices. In 1389 the leader of a flagellant band in Italy called the *bianchi* was burned by order of the pope, and his following dispersed. John Gerson insisted that the flagellants were creating a cultus and ritual of their own in antagonism to those of the church. This view was borne out by the facts, in Germany in 1414, when there was a recrudescence of the epidemic of flagellation which was preached as the only way to salvation. It was suppressed by the Inquisition, but held its ground among the lower ranks of Catholic piety. In the 16th century it subsisted in Italy, Spain and southern France. Henry III. of France met with it in Provence, and attempted to acclimatize it at Paris. Flagellation was occasionally practised as a means of salvation by certain Jansenist convulsionaries in the 18th century. In 1820 a band of flagellants appeared during a procession at Lisbon; and in the Latin countries, at the season of great festivals, one may still see brotherhoods of penitents flagellating themselves before the assembled faithful.

BIBLIOGRAPHY.—For an account of flagellation in antiquity see S. Reinach, *Cultes, mythes et religions* (vol. i. pp. 173-183, 1906), which contains a bibliography of the subject. Also Rufus M. Jones, article "Flagellants" in Hastings' *Encyclopaedia of Religion and Ethics*, vol. vi. 49, and J. A. MacCullough, article "Austerities" (§ 5), *ibid.* vol. ii. 229; H. Haupt, article "Geisselung, Kirchliche" in Herzog-Hauck, *Realencyklopädie*, vol. vi. 432 ff.; W. M. Cooper, *Flagellation and the Flagellants* (1908).

FLAGELLATA, single-celled animals (Protozoa) characterized by the possession of *flagella*—delicate, hair-like, protoplasmic processes which serve as organs of locomotion (functioning similarly to an oar or to the propeller of an aeroplane). For further particulars see PROTOZOA.

FLAGELLATION: see MUTILATIONS AND DEFORMATIONS.

FLAGELLUM, an organ attached to various small animals for the purpose of locomotion. It consists of a long slender filament, anterior in progression, which causes the body to be drawn along by an undulating movement. These vibratile processes come from a distinct basal granula, may be either one or few in number and can move independently of each other. In cases where the body is fixed, the flagellum causes a current towards it by which the animal obtains its food. It also acts as a propeller like the tail of a fish by posterior movement. See CYTOLOGY and PROTOZOA.

FLAGEOLET, in music, a kind of *flûte-à-bec* with a new fingering, invented in France at the end of the 16th century, and in vogue in England from the end of the 17th to the beginning of the 19th century. The flageolet differed from the recorder in that it had four finger-holes in front and two thumb-holes at the back instead of seven finger-holes in front and one thumb-hole at the back. This fingering has survived in the French flageolet still used in the provinces of France in small orchestras and for dance music.

TYPES OF FLAGEOLET

FLAGG, ERNEST (1857—), American architect, was born at Brooklyn (N.Y.), on Feb. 6, 1857. He studied at the École des Beaux-Arts, Paris, and in 1891 began to practise as an architect in New York city. He designed St. Luke's hospital and the Singer building, New York city, whose tower (612ft.) was the highest commercial structure in America at the time of its erection (1908). Other public buildings he designed are the Corcoran Art gallery, Washington (D.C.), and the U.S. Naval academy, Annapolis (Md.). He has also designed many private residences and has lately devoted much attention to the problem of the cheap but durable small house. In this connection he has devised new construction methods. He has written *Small Houses—Their Economic Design and Construction* (1922).

FLAGSTAFF, a city of northern Arizona, U.S.A., at the foot of the San Francisco Peaks, 6,896ft. above sea-level; the county seat of Coconino county. It is on the National Old Trails highway and also Number 89, and on the main line of the Santa Fe railway; and has a municipal airport. The population was 3,891 in 1930. Coconino is the largest county in the United States, more than twice the size of Massachusetts. Nearly 90% of its 18,623sq.m. is under Government supervision, in national forests, parks, monuments and Indian reservations. It contains the largest stand of virgin yellow pine left in the country, and vast deposits of coal and oil, not yet commercially exploited. On its ranges graze 90,000 cattle and 250,000 sheep. Around Flagstaff dry farming is a profitable industry, with potatoes for the leading crop. The city has large lumber mills. It is headquarters for the Coconino National Forest Service; and is the seat of the Northern Arizona State teachers college, the Lowell observatory (where Percival Lowell [*q.v.*] made his studies of Mars), the South-western experiment station of the forestry service, and a large sanatorium for tubercular children. Within easy reach by motor is an extraordinary variety of interesting places, including the Grand Canyon, petrified forests, the Painted Desert, Rainbow and Tonto natural bridges, Meteorite mountain, Mormon lake and Lake Mary, Hopi and Navajo Indian reservations, Montezuma castle (a large, well-preserved cliff dwelling), and the Wupatki ruins of ancient Indian pueblos. Flagstaff took its name from a lofty pine which was stripped of its branches to serve as a pole for the United States flag by a party of engineers who camped here in July 4, 1876.

FLAHAUT DE LA BILLARDERIE, AUGUSTE CHARLES JOSEPH, COMTE DE (1785-1870), French general and statesman, son of Alexandre Sébastien de Flahaut de la Billarderie, comte de Flahaut, beheaded at Arras in February 1793, and his wife Adélaïde Filleul, afterwards Mme. de Souza (*q.v.*), was born in Paris on April 21, 1785. Charles de Flahaut was generally recognized to be the offspring of his mother's liaison with Talleyrand, with whom he was closely connected throughout his life. His mother took him with her into exile in 1792, and they remained abroad until 1798. He entered the army as a volunteer in 1800, and received his commission after the battle of Marengo. He became aide-de-camp to Murat, and was wounded at Landbach in 1805. At Warsaw he met Anne Poniatowski, Countess Potocka, with whom he became intimate. He served at Friedland (1807), in Spain (1808), and then in Germany. Meanwhile the Countess Potocka had established herself in Paris, but Charles de Flahaut was now the lover of Hortense de Beauharnais, queen of Holland by whom he had a son, known later as the duc de Morny (*q.v.*). Flahaut fought in the Russian campaign of 1812, and in 1813 became general of brigade, aide-de-camp to the emperor, and, after the battle of Leipzig, general of division. After Napoleon's abdication in 1814 he was placed on the retired list. The Hundred Days brought him into active service again. A mission to Vienna to secure the return of Marie Louise resulted in failure. He was saved from exile by Talleyrand's influence, but was placed under police surveillance. Presently he settled in England, where he married Margaret Elphinstone, afterward Baroness Keith in her own right. The French ambassador opposed the marriage, and Flahaut resigned his commission. His eldest daughter, Emily Jane, married Henry, 4th marquess of Lansdowne. The Flahauts returned to France in

1827, and in 1830 Flahaut was made a peer of France. He remained intimately associated with Talleyrand's policy, and was, for a short time in 1831, ambassador at Berlin. He was afterwards attached to the household of the duke of Orleans, and in 1841 was sent as ambassador to Vienna, where he remained until 1848, when he was dismissed and retired from the army. After the *coup d'état* of 1851 he was again actively employed, and from 1860 to 1862 was ambassador at the court of St. James. He died on Sept. 1, 1870. The comte de Flahaut is perhaps better remembered for his exploits in gallantry, and the elegant manners in which he had been carefully trained by his mother, than for his public services, which were not, however, so inconsiderable as they have sometimes been represented to be.

See A. de Haricourt, *Madame de Souza et sa famille* (1907).

FLAIL, a farm hand-implement formerly used for threshing corn. It consists of a short thick club called a "swingle" or "swipple" attached by a rope or leather thong to a wooden handle in such a manner as to enable it to swing freely. The "flail" was a weapon used for military purposes in the middle ages. It was made in the same way as a threshing-flail but much stronger and furnished with iron spikes. It also took the form of a chain with a spiked iron ball at one end swinging free on a wooden or iron handle. This weapon was known as the "morning star" or "holy water sprinkler." During the panic over the Popish plot in England from 1678 to 1681, clubs, known as "Protestant flails," were carried by alarmed Protestants.

FLAMBARD, RANULF, or RALPH (d. 1128), bishop of Durham and chief minister of William Rufus, was the son of a Norman parish priest. Migrating at an early age to England, the young Ranulf entered the chancery of William I. He was disliked by the barons, who nicknamed him Flambard in reference to his talents as a mischief-maker. He appears to have played an important part in the compilation of the Domesday survey, in which he is mentioned as a clerk by profession, and as holding land both in Hants and Oxfordshire. Before the death of the old king he became chaplain to Maurice, bishop of London, but early in the next reign Ranulf returned to the royal service. He is usually described as the chaplain of Rufus; he seems in that capacity to have been the head of the chancery and the custodian of the great seal. But he is also called treasurer; and there can be no doubt that he was an agent of the extortion from which all classes suffered between 1087 and 1100. He profited largely by the tyranny of Rufus, farming for the king a large proportion of the ecclesiastical preferments which were illegally kept vacant, and obtaining for himself the wealthy see of Durham (1099). On the accession of Henry I., he was imprisoned, but escaped from the Tower of London. A popular legend represents the bishop as descending from the window of his cell by a rope which friends had conveyed to him in a cask of wine. He took refuge with Robert Curthose in Normandy, and received the administration of the see of Lisieux. After the victory of Tinchebrai (1106) the bishop made his peace with Henry, and was allowed to return to Durham where he passed the remainder of his life. His private life created much scandal, but he distinguished himself, even among the bishops of that age, as a builder and a pious founder. He all but completed the cathedral which his predecessor, William of St. Carilef, had begun; fortified Durham; built Norham Castle; founded the priory of Mottisfont and endowed the college of Christchurch, Hampshire. As a politician he ended his career with his submission to Henry. Ranulf died on Sept. 5, 1128.

See Orderic Vitalis, *Historia ecclesiastica*, vols. iii. and iv. (edit. le Prévost, Paris, 1845); the first continuation of Symeon's *Historia Ecclesiae Dunelmensis* (Rolls ed., 1882); William of Malmesbury in the *Gesta pontificum* (Rolls ed., 1870); and the *Peterborough Chronicle* (Rolls ed., 1861). Of modern writers E. A. Freeman in his *William Rufus* (1882) gives the fullest account.

FLAMBOROUGH HEAD, a promontory on the Yorkshire coast, England, between the Filey and Bridlington bays of the North sea. It is a lofty chalk headland. The cliffs of the Head are pierced with caverns and fringed with rocks of fantastic outline. Sea-birds breed abundantly on the cliffs. A lighthouse marks the point, in 54° 7' N., 0° 5' W.

FLAMBOYANT STYLE, in architecture, the last phase of the Gothic in France, characterized by the dominance in tracery of the line of double curvature, known as the "ogee curve," which generates the flame-like forms that give the name flamboyant to the style. Flamboyant forms begin to appear in the late 14th century, as in one of the chapels of Amiens cathedral (1373); by the middle of the 15th century they were almost universal. Borrowing from the English the idea of the reversed curve and of flowing tracery (see DECORATED PERIOD and GOTHIC ARCHITECTURE), the French developed them with greater freedom. The best flamboyant tracery is often simpler and more direct than the English curvilinear work; grace of form and attenuation of line, a restrained use of cusps and generally slim proportions, are the aims sought. In the 16th century, tracery returned to lower and more stumpy proportions with a great use of round and elliptical arches and circular curves, with frequent barrenness and lack of invention. All work of the flamboyant period is characterized by lavishness of detail, multiplication of miniature niches, fantastic and elaborate crockets, pierced, traceried gables, curved-sided pinnacles and the practice of intersecting and interpenetrating mouldings of different profiles, as, for instance, a cornice and a raking gable mould. Double and triple bases are frequent, the upper bases being penetrated by projecting shafts which have their own bases below. Among the outstanding examples of the style are the church of St. Maclou at Rouen (begun 1432), the west front of Rouen cathedral (1481-92), the northern spire of Chartres cathedral (1512), St. Wulfram at Abbeville (1480), the south transept of Beauvais cathedral (1500-48) and the Palais de Justice at Rouen (c. 1500). (T. F. H.)

FLAME. From the earliest times the phenomenon of flame became invested with a peculiar element of mystery, and little progress was made in elucidating it until a late stage in the history of human knowledge. To people unable to discriminate between things material and immaterial, flame seemed to be a radiant nothingness, a sort of all-devouring element of divine or diabolic significance. At last the prosaic idea gained currency that flame was merely burning smoke. Newton, among others, expressed this view. The fact that when the flames of oil lamps and candles are extinguished a visible smoke trails in the region just where the flame was, and that this smoke can be lit to re-establish the flame, no doubt gave rise to the idea that flame is burning smoke. Very little alteration has to be made in this conclusion in order to render the modern view, namely, that flame is burning gas. The visible smoke of any extinguished flame we now know to be due to the fact that the hot invisible vapour (gas) of the liquid or solid combustible which was feeding the flame gets chilled, and so produces a visible cloud of little drops or solid particles, just as invisible water vapour does when it is chilled. A flame may contain solid matter as well as its burning gas, but it is the burning gas that is the basis of the flame. No doubt the term flame is occasionally used for gases put into a state of glow by some other stimulus than that of the burning process, but in this article we shall use the term flame in the ordinary sense and in reference to the burning of coal-gas and other common combustibles.

The fact that flame is burning gas leads at once to the question of what is meant by "burning," or by the process of combustion. It will suffice here to say that by combustion is usually meant a chemical action between two different substances A and B, in which a large amount of heat is evolved owing to the union of A with B to form a compound AB, or, if A and B are composite bodies, to some exchange of chemical partnership. The heat so generated gives hotness to the gases of the flame, and it might seem also that the light of the flame would be due to the glow of the hot gases. The explanation of the light of flames, as will be seen later, is, however, not quite so simple. The fact that a flame is ordinarily the outcome of a chemical transaction between two gaseous substances A and B gives us the key to explaining the structure of flames. In the first place A and B are equal partners in the transaction, but practically all terrestrial flames are transactions in which the oxygen of the air takes part; thus we get flames by leading other gases into our oxygenated atmosphere and lighting them where they enter. It is easily conceivable that on another

globe what we on earth call combustible gases might form the atmosphere, and in that case flames would be obtained by leading in oxygen or air and igniting it as it entered such an atmosphere. This inversion of the ordinary way of getting a gas flame can easily be shown in a well-known laboratory experiment. It will be seen then that the terms "combustible" and "supporter of combustion" are in some degree misleading, as they suggest a difference of function.

In order that we may have a flame the gas A and the gas B have to become admixed and the temperature has to be raised until ignition takes place. The mixing may occur spontaneously, as when one gas streams into the other, or by the use of some special device. The temperature is usually raised not gradually but by the use of a match or a spark much hotter than is really necessary for the purpose. It is true of all such gas mixtures that there are limits to the proportions within which the mixture will burn and also that the rate of burning will vary according to the proportions of the mixture. These facts are now well-known among those who drive motor-vehicles. In the case of average coal-gas and air at ordinary atmospheric temperature and pressure, mixtures of the two will not inflame if the proportion of coal gas is below about 7% or above 30%. The maximum rapidity of burning—a travel of the flame through the stationary mixture at a rate rather more than one metre per second—is found in a mixture of about 18% of gas and 82% of air.

Simple Flames.—With the foregoing principles in mind, we may begin by supposing a flame of the simplest kind, where a gas A is led into gas B through an ordinary pipe of circular cross section without the addition of any special burner. At the low pressures (3 or 4 in. water gauge) at which gas is usually led into our houses, it will flow out of such a pipe as a cylindrical column, which, rising vertically, becomes mixed with air on its outer surface. If now we apply a light we may expect flame to set in wherever A and B have become mixed in proportions which lie within the limits of inflammability. Considering then the column of ascending gas just where it issues from the tube and is mixing with air on its margin, we may, on applying a light, expect to have a thin ring of flame round it and within this the gas A (which we will assume to be the one being led) almost unmixed with B. This unmixed central shaft of gas is however moving upwards so that in its turn its margin gets mixed with B and burns, and so the process will go on until the ascending column of gas gets burned through. The effect will be in a way like pulling out the successive tubes of a telescope, except that there will be no sudden breaks in the rate of thinning of the column. The fact that the central part of the column of gas has not been subject to friction against the walls of the pipe, and is therefore moving upwards more rapidly than the rest of the gas, must also be remembered. A flame conceived in the foregoing way would then be a hollow conical sheet of burning gases—the sheet being thin and the gas inside unburnt: a flame so produced would therefore be hollow.

The fact that flames—at any rate large flames—are hollow was discovered long since and is strongly emphasized by Francis Bacon who, by thrusting an arrow into a flame and finding it charred only where it passed through the edges, concluded "that flame burneth more violently towards the sides than in the midst; and, which is more, that heat or fire is not violent or furious but where it is checked and pent." Proofs of the hollowness of such flames and their content of unburned gas are easily made. A flame of carbon monoxide gives a uniform blue cone of flame, and if a match head be passed through the cone to the middle, the stick of the match will catch fire whilst the head remains for a considerable time unignited. A simpler experiment is to bring a card horizontally down on to a candle flame until it nearly touches the wick; it will be found that the upper side of the card shows a charred ring. Another simple proof is to lead off the gas from the middle of the flame by an inclined glass tube and to light it at the projecting end. The appearance of some flames, however, is deceptive. The flat flame given by the old fashioned gas-burner consists of thin sheets of flame, whose hollowness can be demonstrated without much difficulty. The bright yellow part of a candle flame looks as if it went right through the flame but is

really an exceedingly thin sheet.

Apart from the question of shape, the actual appearance of a flame varies according to the nature of the gases A and B that are used in producing it and the variety of chemical changes taking place. In the flame of hydrogen we have no reason to believe that there is any difference in the chemical processes taking place in different parts of the flame. Hydrogen and the oxygen of the air are throughout entering into chemical union to form water. With carbon monoxide the same chemical transaction—the union of the gas with oxygen to form carbon dioxide—is taking place everywhere in the flame. These flames therefore have the appearance of uniformity. But in the case of combustible gases of a more complex character, where the process of burning may take place in stages and where incidental chemical changes ensue, the flame loses its uniformity and becomes differentiated into distinct zones. The flame of coal gas, oil, tallow, wood, paper, string and in fact of all ordinary combustible bodies shows a differentiated structure. There is a distinctly blue part of no great luminosity and a distinctly yellow part of considerable brightness, to which the light is mainly due. The fact that the combustible substance in these cases contains at least two combustible elements, carbon and hydrogen, the first of which can burn in two stages, and the further fact that the gases enclosed in these flames undergo chemical changes when subject to a mere baking process from the burning walls, account, as we shall see, for the complexity in the structure of these flames.

Air-fed Flames.—A second type of flame is produced when a combustible gas is mixed by some special device with the air or oxygen necessary for its complete combustion and then ignited. This is achieved by the use of a "blowpipe" or "blast-burner"; a jet of air is sent into the combustible gas as it escapes from the wick or burner. The burning is accordingly completed much more quickly than when an unmixed combustible gas has to wander into the air in order gradually to find its oxygen; and so the region of combustion becomes also much smaller and much hotter. The flame in this case is burning through and through and does not consist of a mere sheet with unburned gas within. Its structure is very simple, the velocity of the gaseous stream makes the flame narrow, long, and pointed, and there is only a small conical region within it where the velocity of the mixture is so great that the flame cannot travel against it.

In using the blowpipe for producing a hot flame we force in just enough air for complete combustion; more air would only reduce the temperature. Less air would do the same, but it also gives a character to the flame which is desired when the blowpipe is being used for some special chemical or industrial purposes. When the blowpipe supplies oxygen instead of air we get rid of the diluting atmospheric nitrogen, which has four times the bulk of the oxygen and takes no part in the combustion. The flame therefore becomes still smaller and much hotter, the combustion being, as it were, still further condensed. The hottest flame we can produce on a practical scale is that produced by burning with oxygen in a blowpipe the gas acetylene (*q.v.*), and this flame is now largely used as a source of intense heat for welding and cutting iron and steel.

A third type of flame is that associated with the name of the great German chemist, R. W. Bunsen, who in 1855 devised his well-known burner for use in chemical laboratories. The object was to mix coal-gas before it issued from the burner with sufficient air, not for complete combustion, but enough to make it burn blue. The construction is shown in fig. 1, which is reproduced from Bunsen's original publication. The gas is led by a side-tube to the burner where it issues through a small punctured nipple into an upright tube. At the base are circular openings which in the usual form of burner can be varied in size or altogether closed by turning a metal collar. The passage of the jet of gas past these openings sucks in air, and if a light is applied at the top of the

FIG. 1.

TYPES OF FLAME STRUCTURE

air sent into coal gas as it escapes from burner. The pointed shape makes this flame useful in many ways, principally for soldering, welding, cutting metals, brazing, etc. 4-8. Bunsen flame, consisting of two conical sheets. When adjusted, the outer and hotter flame is pale blue, the inner flame yellowish red. Figures 4 to 8 show variations of flame when the same amount of gas is used but the amount of air is increased until it is about half that required for complete combustion

1. Simplest type of flame, a hollow conical sheet of burning gases, nearly invisible, and very hot, showing almost complete combustion. This flame is produced by carbon monoxide issuing into the air through a tube, lit at the orifice. 2. Candle flame, a shell of flame containing glowing solid particles of carbon which produce the bright glow. The blue "calyx" at base and bluish mantle surrounding flame are hardly visible in the photograph. 3. Blowpipe flame, a sharp conical flame burning throughout, due to a jet of

burner a flame is given which, as the saying is, "burns blue" and does not blacken objects to which it is applied. This principle has been applied to the construction of many different shapes of burners used with the gas mantle for lighting, and for innumerable purposes of heating in gas fires, cookers, furnaces and a great variety of scientific and industrial appliances. They are often called "atmospheric burners" to distinguish them from burners where the gas is burned without air being admitted to it in the burner tube.

In burners of the Bunsen type it will be noticed that when the air-ports are closed the flame has the same character as that of a candle, while when they are gradually opened the flame loses its yellow luminosity and soon becomes wholly "blue." This blue flame does not at first show a very clearly differentiated structure, but as the air-ports are opened more widely the flame acquires a plainly evident double structure. There is a distinct inner cone of flame, and outside this a sheet of flame of a slightly bulged conical form; with further increase of air the inner cone becomes smaller, more sharply defined and greener in colour. If the air supply is carried beyond this stage the inner cone shows signs of instability in a tendency to retreat into the burner-tube and in the end will actually do so, and passing down the tube will light the gas at the nipple. The burner is now out of order and the gas is burning within the tube with an amount of air insufficient for its complete combustion. There may or may not be a second flame at the top of the tube where the combustion is completed. If there is not, the half-burned gas escapes and the malodorous and poisonous constituents contaminate the surrounding air. When the burner is in this condition the gas must be turned off and only re-lighted after the air-ports have been adjusted to give a smaller supply of air. The retreat of the inner cone down the burner tube ("lighting back," or "back-firing") in the case of long or large burners such as those of an ill-adjusted gas fire has the character of a small explosion. The principles of the Bunsen burner and the characteristics of the flames of atmospheric burners can be readily understood by use of the "Flame Separator," shown in fig. 2.

This apparatus consists of two tubes (best made of silica ware) arranged telescopically so that the wider tube will easily slide, gas-tight, up and down the narrower one. When the separator is fixed to a Bunsen burner with closed airports and the gas is ignited, a luminous flame is obtained, and if the ports are gradually opened this acquires a clearly two-coned structure. With further air supply the rate of inflammation of the mixture will eventually reach a state at which it is greater than the rate of up-flow of gases in the wider tube. The inner cone accordingly travels downwards against the stream until it reaches the mouth of the narrower tube, where the gas stream is more rapid, and there will remain if the air supply be kept steady. The outer cone remains at the mouth of the wider tube. On sliding down the wider tube until its mouth is below that of the narrower one, the normal two-coned flame is established at the mouth of the narrower tube.

It is clear that in the atmospheric burner combustion takes place in two stages. If more air be admitted to the flame in the stage last described, the rate of inflammation will soon exceed that of the upward velocity of the gases and the inner cone will enter the narrow tube, travel down it, and ignite the gas at the nipple. A further phase of the flame cannot be obtained with the ordinary Bunsen burner, but by supplying air under pressure and gas by means of a T-piece to the separator the supply of air may be made greater than is necessary for complete combustion. The rate of travel of flame through the mixture then begins to fall and reaches a point at which it is no greater than the rate of upward flow of the gases. At this point a stable flame may be obtained at the mouth of the separator, in which complete combustion is taking place independently of the outside air. The

FIG. 2.

flame is therefore single-coned and of the blowpipe type. A further supply of air merely dilutes and cools the flame until it is finally extinguished. The first phases of flame are illustrated in figs. 4-8 of the Plate.

Much ingenuity has been expended on the construction of atmospheric burners so as to adapt them for special uses, and several types have become well-known by the names of their inventors. The aim may be to adapt the burner for use in lighting with a Welsbach mantle, in which case the hottest possible shell of flame in which the mantle can be bathed is desired. The best known upright burner in this connection is known as the "Kern," but it has been largely superseded by the inverted burner in which the flame is projected down into a mantle (fig. 3). By this inversion a higher duty is obtained from the gas and the inconvenience of any shadow of the burner is avoided. In designing burners for heating purposes, as for a gas fire, care has to be taken to obtain a set of noiseless flames, which are of the same dimensions and adjustable so as to give the right degree of aeration. The fire-clay "fuel" fits over the flames so as to be bathed in flame without actual contact with the inner cone.

It is important to remember that in an atmospheric burner consuming coal-gas the region between the two cones of the flame is rich in carbon monoxide, and that if in the use of such flames there is any intrusion into the inner cone by the object which is being heated, there is liability of the escape of carbon monoxide, so that if there is no flue provided there may in such circumstances be very undesirable and dangerous contamination of the air in an apartment.

The Source of Light in Flames.—As already stated, the light of flames may come either from glowing gas alone or from this with the added glow of solid particles occurring in the flame. The light from the glowing gas alone is in the most familiar cases, such as hydrogen and carbon monoxide, not intense. It must suffice here to say that it may be regarded as a flash accompanying chemical action. In the flames of common combustibles containing carbon, the bright yellow glow was shown by Humphry Davy to be due to "the deposition of solid charcoal which, first by its ignition and then by its combustion, increases in a high degree the intensity of the light." This solid charcoal in almost infinitely fine particles is, according to modern views, separated in the flame by a very simple process.

In a candle flame the combustible gas is supplied by the wick which brings up from the little pool at the top of the candle a

BY COURTESY OF "THE WELSBACK LIGHT CO.

FIG. 3

steady supply of melted paraffin wax. The wick being in the form of a flat band bends over so that its tip gets into the air and burns with a red glow. It thus remains constant in size and does not require the periodical snuffing which was one of the troubles of the old straight-wicked tallow candles. In lighting a candle the heat of the match flame melts and vaporizes a little of the paraffin and the flame thus produced continues to maintain a pool of melted wax at the top of the candle. The flame of the candle exhibits three distinct regions; within the flame is what we may call "candle-gas" streaming from the wick and becoming mixed on its outer borders with the atmospheric air. When the mixture has attained certain proportions it becomes ignitable; this occurs long before the admixture of air is sufficient for complete combustion.

The region where the candle gas is first ignited is clearly evident at the base of the flame where a thin sheet of bright blue colour is situated like the calyx of a flower; it shades off about a quarter of the way up the flame. Outside this bright blue calyx there will be seen a fainter region of flame, and in this the incompletely

burned gas is finding air sufficient for the completion of the burning process. This faint sheath or mantle extends round the whole flame from top to bottom. It is not easy to see it all in a candle unless the glare of the yellow part is masked by a screen, but it can usually be well seen in the flame of a piece of string. These two parts of a candle flame really correspond to the two cones of a Bunsen flame; the combustible gas is burning in two stages or in two sheets, which are quite close together in the case of the candle. Within this "blue burning" part of the flame is candle-gas streaming from the wick and being subject to a roasting process as it ascends. Now it may be said generally of carbonaceous gases that when they are strongly heated in absence of air they deposit charcoal, so that in this we find a reason why, as the candle-gas gets heated within the blue burning walls of flame, it begins to yield particles of carbon. Not only are these particles hot but as soon as they reach enough air they burn with a bright glow, and thus we have a sheet of bright yellow luminosity which shows a maximum glow about half-way up the flame. Where the particles are sparse the glow is feeble; where they are superabundant, as may be the case near the tip of the flame, the glow is dull and merely ruddy, or indeed some of the particles may escape unburned as smoke.

This explanation of the structure of a candle flame may be verified by simple observations of a small coal-gas flame as it is turned down until the yellow part of the flame has entirely disappeared, or when, before the yellow part has disappeared, a ring of wire is placed in the blue walls. The cooling effect at once suppresses the separation of carbon and the yellow patch of light disappears. (See also COMBUSTION; and SPECTROSCOPY.)

(A. SM.)

FLAMEN, from *flare*, "to blow up" the altar fire, a Roman sacrificial priest. The flamens were subject to the pontifex maximus and were consecrated to the service of some particular deity. The highest in rank were the *flamen Dialis*, *flamen martialis* and *flamen quirinalis*, who were always patricians. When the number of flamens was raised from three to 15, those already mentioned were entitled *maiores*; the other 12, called *minores*, were chosen from the *plebs*. Towards the end of the republic the number of the lesser flamens diminished. The flamens were elected for life, but they might be compelled to resign for neglect of duty, or on the occurrence of some ill-omened event during the performance of their rites. The characteristic dress of the flamens was the *apex*, a white conical cap, the *laena* or mantle, and a laurel wreath. The official insignia of the *flamen Dialis* (of Jupiter), the highest of these priests, were the white cap (*pileus, albogalerus*), at the top of which was an olive branch and a woollen thread; the *laena*, a thick woollen *toga praetexta* woven by his wife; the sacrificial knife; and a rod to keep the people from him when on his way to offer sacrifice. He was entitled to a seat in the senate and a curule chair. The sight of fetters being forbidden him, his house was a sanctuary for a prisoner, and a criminal who met him in the street was respited. He was not allowed to leave the city for a single night, to ride or even touch a horse, to swear an oath, to look at an army, to touch anything unclean, or to look upon people working. His marriage, performed with the ceremonies of *confarreatio* (*q.v.*), was dissoluble only by death, and on the death of his wife (called *flaminica Dialis*) he was obliged to resign his office. The *flaminica Dialis* assisted her husband at the sacrifices and other religious duties which he performed. The main duty of the flamens was the offering of daily sacrifices; on Oct. 1 the three *maiores* drove to the Capitol and sacrificed to *Fides Publica* (the Honour of the People).

Distinct from the above were the *flamen curialis*, who assisted the *curio* with the religious affairs of each *curia* (*q.v.*), the flamens of various sacerdotal corporations, such as the Arval Brothers (*q.v.*), and the *flamen Augustalis*, who superintended the worship of the emperor in the provinces.

See the exhaustive article by C. Jullian in Daremberg and Saglio, *Dictionnaire des antiquités*; also J. E. Sandys, *Companion to Latin Studies* (1921).

FLAMETHROWER. This weapon was first used by the Germans in the winter of 1914-15, and with marked success in

the Bois d'Avocourt (Verdun) on Feb. 26, 1915 (Ger. *Flammenwerfer*). The French followed in their use. The British used them on the Somme and in the Zeebrugge attack, St. George's Day, 1918. The American Expeditionary Force did not use them at all. Their value was chiefly moral.

Structure.—A flamethrower consists of (a) the container filled with some mixture of heavy and light oils, (b) the strong walled vessel filled with air, nitrogen, CO₂, etc., under high pressure, and (c) a discharge tube, with nozzle and, in most cases, an ignition device. Between (a) and (b) is a reducing valve, and between (b) and the nozzle a firing valve or trigger. Flamethrowers were short-range weapons, and were of two types, the heavy and the portable. The heavy type attained an extreme range of 134 yd. (British model), while with the portable British model a range of 45 yd. was attained, and maintained some 15 to 18 shots from a single filling of three gallons. The most satisfactory propellant was found to be nitrogen—either the pure product or a "deoxygenated air" produced in one field by a mobile plant. (See also GREEK FIRE.)

FLAMINGO, the name given to birds of the genus *Phoenicopterus*. The common flamingo, *P. roseus*, is in both sexes white in colour, with a rosy tinge above, the wings scarlet, bordered with black (as in all species). The legs of all these birds are very long, the feet webbed, the neck long and the beak bent in the middle. *P. roseus* ranges from the Cape Verde Islands to India and Ceylon, reaching Lake Baikal in the north and Madagascar in the south. It is replaced in South Africa by *P. minor*. A third species, *P. ruber*, light vermilion in colour, inhabits America from Florida to Para, while two other species also occur in South America. Fossil flamingoes have been found in the Lower Miocene of France and the Pliocene of Oregon and in later rocks.

The food of these birds consists of the small aquatic invertebrates, living in the mud of lagoons; these the bird sifts out with its bill, the roomy lower jaw being furnished with numerous lamellae. The head is held upside down when feeding. When flying the neck is stretched out straight. The nest is built of mud, and is a conical structure rising a few inches out of the water—if the latter subsequently sinks, it may be much higher. One or two chalky white eggs are laid and the young have a straight bill, short legs and white down. The bird sits in the normal way, with the legs doubled up under it.

FLAMINIA, VIA, the chief ancient northward high road of Italy, made by C. Flaminius (220 B.C.). Augustus, when he instituted a general restoration of the roads of Italy, which he assigned for the purpose among various senators, reserved the Flaminia for himself, and rebuilt all the bridges except the Pons Mulvius, by which it crosses the Tiber, 2 m. N. of Rome (built by M. Scaurus in 109 B.C.) and an unknown Pons Minucius. Triumphal arches were erected in his honour on the former bridge and at Ariminum, the latter of which is still preserved. Vespasian constructed a new tunnel through the pass of Intercisa, the modern Furlo, in A.D. 77 (see CALES), and Trajan repaired several bridges.

The course of the Via Flaminia is due north from Rome, through difficult country, passing slightly east of the site of the Etruscan Falerii, through Oriculi and Narnia. Here it crossed the Nar by a splendid four-arched bridge to which Martial alludes, one arch of which and all the piers are still standing; and went on, followed at first by the modern road to Sangemini which passes over two finely preserved ancient bridges, past Carsulae to Mevania, and thence to Forum Flaminii. Later on a more circuitous route from Narnia to Forum Flaminii was adopted, passing by Interamna, Spoletium and Fulginium (from which a branch diverged to Perugia), and increasing the distance by 6 m. The road thence went on to Nuceria and Helvillum, and then crossed the main ridge of the Apennines, a temple of Jupiter Apenninus standing at the summit of the pass. Thence it descended to Cales (where it turned northeast), and through the pass of Intercisa to Forum Sempronii (Fossombrone) and Forum Fortunae, where it reached the coast of the Adriatic. Thence it ran northwest through Pisaurum to Ariminum. The total distance from Rome was 209 m. by the older road and 215 by the newer. The road gave its name to a juridical district of Italy from the 2nd century A.D. onwards,

the former territory of the Senones, which was at first associated with Umbria (with which indeed under Augustus it had formed the sixth region of Italy), but which after Constantine was always administered with Picenum.

See T. Ashby and R. A. L. Fell in *Journal of Roman Studies*, xi. (1921), 125 seq. for a full account of this road. (T. A.)

FLAMININUS, TITUS QUINCTIUS (c. 228–174 B.C.), Roman general and statesman. He was military tribune under M. Claudius Marcellus, the conqueror of Syracuse. In 199 he was quaestor, and consul the next year.

Flamininus was one of the first and most successful of the rising school of Roman statesmen, the opponents of the narrow patriotism of which Cato was the type, the disciples of Greek culture, and the advocates of a wide imperial policy. His personal charm, his knowledge of men, and his intimate knowledge of Greek, all marked him out as the fittest representative of Rome in the East. Accordingly, the province of Macedonia, and the conduct of the war with Philip V. of Macedon were assigned to him. Flamininus modified both the policy and tactics of his predecessors. He spent most of his first year in gaining control of Greece by diplomacy and force. Hostilities were renewed in the spring of 197, and Flamininus took the field supported by nearly the whole of Greece. At Cynoscephalae the Macedonian phalanx and the Roman legion met for the first time. It was a victory of superior tactics. The left wing of the Roman army was retiring before the Macedonian right led by Philip when Flamininus charged the left wing under Nicanor, which he caught still forming, and cut it to pieces. This defeat was turned into a general rout by a nameless tribune, who collected twenty companies and charged in the rear the victorious Macedonian phalanx. Macedonia was now at the mercy of Rome, but Flamininus contented himself with his previous demands. Philip lost all his foreign possessions, but retained his Macedonian kingdom almost entire. He was required to reduce his army, to give up all his decked ships except five, and to pay an indemnity of 1,000 talents (£244,000). At the Isthmian games a herald proclaimed to the assembled crowds that "the Roman people, and T. Quinctius their general, having conquered King Philip and the Macedonians, declare all the Greek states which had been subject to the king henceforward free and independent." Flamininus's last act before returning home was to ask the Achaeans to ransom the Italian captives who had been sold as slaves in Greece during the Hannibalic War. These, to the number of 1,200, were presented to him on the eve of his departure (spring, 194), and formed the chief ornament of his triumph.

In 192, on the rupture between the Romans and Antiochus III. the Great, Flamininus returned to Greece as the civil representative of Rome. He secured the wavering Achaean states, cemented the alliance with Philip, and contributed largely to the Roman victory at Thermopylae (191). In 183 he undertook an embassy to Prusias, king of Bithynia, to induce him to deliver up Hannibal, who forestalled his fate by taking poison. Nothing more is known of him.

There seems no doubt that Flamininus was actuated by a genuine love of Greece and its people. To attribute to him a Machiavellian policy, which foresaw the overthrow of Corinth fifty years later and the conversion of Achaëa into a Roman province, is absurd. There is more force in the charge that his Hellenic sympathies prevented him from seeing the innate weakness and mutual jealousies of the Greek states of that period, whose only hope of peace and safety lay in submitting to the protectorate of the Roman republic.

His life has been written by Plutarch, and in modern times by F. D. Gerlach (1871); see also Mommsen, *Hist. of Rome* (Eng. tr.), bk. iii. chs. 8, 9.

FLAMININUS, GAIUS, Roman statesman and general, of plebeian family. During his tribuneship (232 B.C.), in spite of the determined opposition of the senate and his own father, he carried a measure for distributing among the plebeians the *ager Gallicus Picenus*, an extensive tract of newly-acquired territory to the south of Ariminum (Cicero, *De senectute*, 4, *Brutus*, 14). In 223, when consul with P. Furius Philus, he took the field against

the Gauls, who were said to have been roused to war by his agrarian law. Having crossed the Po to punish the Insubrians, he at first met with a severe check and was forced to capitulate. Reinforced by the Cenomani, he gained a decisive victory on the banks of the Addua. He had previously been recalled by the optimates, but ignored the order. The victory seems to have been due mainly to the admirable discipline and fighting qualities of the soldiers; the decree of the senate against his triumph was overborne by popular clamour. His name is further associated with two great works. He erected the Circus Flaminius on the Campus Martius, for the accommodation of the plebeians, and continued the military road from Rome to Ariminum, which had hitherto only reached as far as Spoletium (see FLAMINIA, VIA). He probably also instituted the "plebeian" games. In 218, as a leader of the democratic opposition, Flamininus was one of the chief promoters of the measure which debarred senators from commercial speculation (Liv. xxi. 63). His support of this measure vastly increased the popularity of Flamininus with his own order, and secured his second election as consul in the following year (217), shortly after the defeat of T. Sempronius Longus at the Trebia. He hastened at once to Arretium, the termination of the western high road to the north, to protect the passes of the Apennines, but was defeated and killed at the battle of the Trasimene lake (see PUNIC WARS).

The testimony of Livy (xxi., xxii.) and Polybius (ii., iii.)—no friendly critics—shows that Flamininus was a man of ability, energy and probity. A popular and successful democratic leader, he cannot, however, be ranked among the great statesmen of the republic. As a general he was headstrong and self-sufficient and seems to have owed his victories chiefly to personal boldness favoured by good fortune. He was certainly to blame for the Trasimene disaster.

His son, GAIUS FLAMININUS, was quaestor under P. Scipio Africanus the elder in Spain in 210, and took part in the capture of New Carthage. In 187 he was consul with M. Aemilius Lepidus, and built the branch of the Via Aemilia connecting Bononia with Arretium. In 181 he founded the colony of Aquileia.

FLAMMARION, NICOLAS CAMILLE (1842–1925), French astronomer, was born at Montigny-le-Roi, Haute Marne, on Feb. 25, 1842. He studied theology at Langres and Paris but was attracted to astronomy, and at the age of 16 he wrote a manuscript of 500 pages *Cosmologie Universelle*; this was the foundation of one of his later works, *La monde avant la création de l'homme*. He became a computer at the Paris observatory (1858–62) and at the Bureau des Longitudes (1862–65). He returned to the Paris observatory in 1867, where he took charge of a large telescope for the measurement of double stars. In 1882 an admirer, M. Méret, presented Flammarion with an estate and chateau at Juvisy, near Paris; here he installed and equipped a private observatory to which he added later a meteorological and climatological station.

Flammarion was interested in making observations with the telescope; he mapped Mars many times and made a number of observations on the moon. In 1879 he drew attention to the changes in colour of the crater Plato and explained them on the assumption of the presence of a primitive vegetation. He observed a number of double stars and computed their orbits, he also observed a number of cases of star drift.

More important, perhaps, than his actual observations was his effort to encourage and popularize the study of astronomy. Flammarion was a fine imaginative writer and he wrote a number of books which made astronomy interesting and intelligible to the lay reader. *L'Astronomie Populaire* (1879, translated into English by J. E. Gore, 1894) is the one best known to English readers; it gained the Montyon prize of the Paris Académie. Flammarion also edited a number of scientific and astronomic reviews. He began to edit *Cosmos* in 1862 and *Annuaire Astronomique*, which was an almanac and astronomical review, in 1864. He also edited *Siècle* and in 1882 he founded the review *L'Astronomie*. In addition to his writing Flammarion encouraged a number of amateur observers at Juvisy, and in 1887 founded the Société Astronomique de France. His services in popularizing interest in astron-

omy were acknowledged in 1922 by the award of Commander of the Legion of Honour. Towards the end of his life Flammarion wrote on psychical research. He died in Paris on June 4, 1925.

His books have been translated into many languages and some have run into as many as 100 editions; amongst them are *Histoire du ciel* (1867); *Contemplations scientifiques* (1869); *Navigation aérienne* (1869); *L'Atmosphère* (1872); *La pluralité des mondes habités* (1875); *Les mondes imaginaires et les mondes réels* (1875); *Les Merveilles célestes* (1875); *Études sur l'astronomie* (9 vols., 1867-80); *Dieu dans la Nature* (1875). (E. Tr.)

FLAMSTEED, JOHN (1646-1719), English astronomer, was born at Denby, near Derby, on Aug. 19, 1646. He was educated at the free school of Derby, but was forced to leave in May 1662, because of bad health. During his illness he began to study astronomy. He read all the books on the subject that he could buy or borrow; observed a partial solar eclipse on Sept. 12, 1662; and attempted the construction of measuring instruments. A paper embodying his calculations of appulses to stars by the moon, which appeared in the *Philosophical Transactions* (iv. 1099), signed *In Mathesti a sole fundes*, an anagram of "Johannes Flamsteedius," secured for him, from 1670, general scientific recognition.

In 1670 he became acquainted with Isaac Newton at Cambridge, entered his name at Jesus college, and four years later, took a degree of M.A. by letters-patent. An essay composed by him in 1673 on the true and apparent diameters of the planets furnished Newton with data for the third book of the *Principia*, and he fitted numerical elements to J. Horrock's theory of the moon. Flamsteed was appointed "astronomical observator" by a royal warrant dated March 4, 1675. He was presented by Lord North in 1684 to the living of Burstow in Surrey; his financial position was further improved by a small inheritance in 1688. He now ordered a mural arc, with which he began to observe systematically on Sept. 12, 1689 (see *ASTRONOMY: History*). The latter part of Flamsteed's life passed in a turmoil of controversy regarding the publication of his results. He struggled to withhold them until they could be presented in a complete form; but they were urgently needed for the progress of science. Newton led the movement for immediate communication; whence arose much ill-feeling between him and Flamsteed. At last, in 1704, Prince George of Denmark undertook the cost of printing; and although the prince died in 1708, and in spite of Flamsteed's objections, the work was printed. The *Historia coelestis*, embodying the first Greenwich star-catalogue, together with the mural arc observations made 1689-1705, was issued under Edmund Halley's editorship in 1712. Flamsteed denounced the production as surreptitious; he committed to the flames three hundred copies; and, in defiance of bodily infirmities, vigorously prosecuted his designs for the entire and adequate publication of his materials. He died on Dec. 31, 1719. The preparation of his monumental work, *Historia coelestis Britannica* (3 vols. folio, 1725), was finished by his assistant, Joseph Crosthwait, aided by Abraham Sharp. The first two volumes included the whole of Flamsteed's observations at Derby and Greenwich; the third contained the *British Catalogue* of nearly 3,000 stars. A portrait of Flamsteed, painted by Thomas Gibson in 1712, hangs in the rooms of the Royal Society. The extent and quality of his performance were the more remarkable considering his severe physical sufferings, his straitened means, and the antagonism to which he was exposed.

BIBLIOGRAPHY.—Francis Baily's *Account of the Rev. John Flamsteed* (1835) is the leading authority for his life. It comprises an autobiographical narrative pieced together from various sources, a large collection of Flamsteed's letters, a revised and enlarged edition of the *British Catalogue*.

FLANDERS (Flem. *Vlaanderen*), a name originally applied only to Bruges and neighbourhood but in the 8th and 9th centuries extended to the coast region from Calais to the Scheldt. In the middle ages this was divided into two parts, one looking to Bruges, the other to Ghent. The name is retained in the two Belgian provinces of West and East Flanders.

1. West Flanders borders the North Sea, and its coast extends from the French to the Dutch frontier for a little over 40 miles. Its capital is Bruges, and the principal towns are Ostend, Courtrai, Furnes, Thielt, Ypres and Roulers. There are fine market gardens and fishing employs a large coast population. There are 31 cantons and 252 communes. Area 1,263 sq. miles. Pop. (1925), 865,006.

2. East Flanders lies east and north-east of the western province, and extends north to near Antwerp. It is more productive than West Flanders, and is well watered by the Scheldt. The district of Waes, entirely reclaimed within the memory of man, is said to be the most productive district of its size in Europe. The principal towns are Ghent (capital), St. Nicolas, Alost, Termonde, Eecloo and Oudenarde. There are 34 cantons and 297 communes. Area 1,172 sq. miles. Pop. (1925) 1,119,591. (X.)

HISTORY

The ancient territory of Flanders comprised not only the modern provinces known as East and West Flanders, but the southernmost portion of the Dutch province of Zeeland and a considerable district in north-eastern France. In the time of Caesar it was inhabited by the Morini, Atrebates and other Celtic tribes, but in the centuries that followed the land was repeatedly overrun by German invaders, and finally became a part of the dominion of the Franks. After the break-up of the Carolingian empire Flanders was attached to the West Frankish monarchy (France). It thus acquired a position unique among the provinces of the territory known in later times as the Netherlands, which were included in that northern part of Austrasia assigned on the death of the emperor Lothaire (855) to King Lothaire II., and from his name called Lotharingia or Lorraine.

The first ruler of Flanders of whom history has left any record is Baldwin, surnamed *Bras-de-fer* (Iron-arm), who married Judith, daughter of the emperor Charles the Bald and was created by him margrave of Flanders. The Northmen were at this time continually devastating the coast lands, and Baldwin was entrusted with the defence of this outlying borderland of the west Frankish dominion. His son, Baldwin II., from his stronghold at Bruges, maintained, like his father, a vigorous defence of his lands against the incursions of the Northmen. On his mother's side a descendant of Charlemagne, he strengthened the dynastic importance of his family by marrying Aelfthryth, daughter of Alfred the Great. On his death in 918 his possessions were divided between his two sons Arnulf the Elder and Adalulf, but the latter survived only a short time and Arnulf succeeded to the whole inheritance. His reign was filled with warfare against the Northmen. In his old age he placed the government in the hands of Baldwin, his son by Adela, daughter of the count of Vermandois, and the young man in a short reign did much for the commercial and industrial progress of the country, setting up the first weavers and fullers at Ghent, and instituting yearly fairs at Ypres, Bruges and other places.

On Baldwin III.'s death in 961 the old count resumed control and spent the few remaining years of his life in securing the succession of his grandson Arnulf II., who died in 989. He was followed by his son Baldwin IV., who fought successfully both against the Capetian king of France and the emperor Henry II. Henry found himself obliged to grant to Baldwin IV. in fief Valenciennes, the burgraveship of Ghent, the land of Waes and Zeeland. The count of Flanders thus became a feudatory of the empire as well as of the French crown. The French fiefs are known in Flemish history as Crown Flanders (*Kroon-Vlaanderen*), the German fiefs as Imperial Flanders (*Rijks-Vlaanderen*). His successor, Baldwin V. (1036-67), greatly extended his power. He obtained from the emperor Henry IV. the territory between the Scheldt and the Dender as an imperial fief, and the margravate of

Antwerp. So powerful had he become that on the decease of Henry I. of France in 1060 he was appointed regent during the minority of Philip I. (*see* FRANCE). Before his death he saw his eldest daughter Matilda (d. 1083) sharing the English throne with William the Conqueror, his eldest son Baldwin of Mons in possession of Hainaut in right of his wife Richilde, heiress of Regnier V. (d. 1036) (*see* HAINAUT), and his second son, Robert the Frisian, regent (*voogd*) of the county of Holland during the minority of Dirk V., whose mother Robert had married (*see* HOLLAND). On his death in 1067 his son Baldwin of Mons, already count of Hainaut, succeeded to the countship of Flanders. Baldwin V. had granted to Robert the Frisian on his marriage in 1063 his imperial fiefs. His right to these was disputed by Baldwin VI., and war broke out between the two brothers. Baldwin was killed in battle in 1070. Robert now claimed the tutelage of Baldwin's children and obtained the support of the emperor Henry IV., while Richilde, Baldwin's widow, appealed to Philip I. of France. The contest was decided at Bavenshoven, near Cassel, on Feb. 20, 1071, where Robert was victorious. Richilde was taken prisoner and her eldest son Arnulf III. was slain. Robert obtained from Philip I. the investiture of Crown Flanders, and from Henry IV. the fiefs which formed Imperial Flanders.

The second son of Richilde was recognized as count of Hainaut (*see* HAINAUT), which was thus after a brief union separated from Flanders. Robert died in 1093, and was succeeded by his son Robert II., who acquired great renown by his exploits in the first crusade. He returned to Flanders in 1100, fought with his suzerain Louis VI. of France against the English, and was drowned in 1111. His son and successor, Baldwin VII., died at the age of 27 from the wound of an arrow, in 1119, leaving no heir. He nominated as his successor his cousin Charles, son of Knut II. of Denmark and of Adela, daughter of Robert the Frisian. Charles tried his utmost to put down oppression and to promote the welfare of his subjects, and obtained the surname of "the Good." His determination to enforce the right made him many enemies, and he was foully murdered on Ash Wednesday, 1127, at Bruges. He died childless, and there were no less than six candidates to the countship. The contest lay between two of these, William Clito, son of Robert of Normandy and grandson of William the Conqueror and Matilda of Flanders, and Thierry or Dirk of Alsace, whose mother Gertrude was a daughter of Robert the Frisian. William was killed before Alost, and Thierry then became count without further opposition. He married the widow of Charles the Good and proved himself at home a wise and prudent prince, encouraging the growth of popular liberty and of commerce. In 1146 he took part in the second crusade; in 1157 he resigned the countship to his son Philip of Alsace and betook himself once more to Jerusalem. On his return from the East 20 years later Thierry retired to a monastery to die in his own land.

Count Philip of Alsace did much to promote the growth of the municipalities for which Flanders was already becoming famous. Ghent, Bruges, Ypres, Lille and Douai under him made much progress as flourishing industrial towns. He also conferred rights and privileges on a number of ports, Hulst, Nieuwport, Sluis, Dunkirk, Axel, Damme, Gravelines and others. But while encouraging the development of the communes and "free towns," Philip sternly repressed any spirit of independence. He acted for a time as regent in France during the minority of his godson, Philip Augustus, whom he married to his niece Isabella of Hainaut (1180). Philip took part in the third crusade and died in the camp before Acre in 1191.

Union with Hainaut.—As he had no children the succession passed to Baldwin of Hainaut, who had married Philip's sister Margaret. The countships of Flanders and Hainaut were thus united under the same ruler. Baldwin did not obtain possession of Flanders without strong opposition on the part of the French king, and he was obliged to cede Artois, St. Omer, Lens, Hesdin and a great part of southern Flanders to France, and to allow Matilda of Portugal, the widow of Philip of Alsace, to retain certain towns in right of her dowry. Margaret died in 1194 and Baldwin in the following year, and their eldest son Baldwin IX. succeeded to both countships. Baldwin IX. is famous in history

as the founder of the Latin empire at Constantinople. He perished in Bulgaria in 1206. His two daughters were both under age, and the government was carried on by their uncle, Philip, marquess of Namur, whom Baldwin had appointed regent on his departure to Constantinople. Philip allowed his nieces to fall into the hands of Philip Augustus, who married the elder sister, Johanna of Constantinople, to his nephew Ferdinand of Portugal. The Flemings were averse to the French king's supremacy, and Ferdinand, who acted as governor in the name of his wife, joined himself to the confederacy formed by Germany, England and the leading States of the Netherlands against Philip Augustus. Ferdinand was, however, taken prisoner at the disastrous battle of Bouvines (1214) and was kept for 12 years a prisoner in the Louvre. The countess Johanna ruled the united countships with prudence and courage until her death, without heir, in 1244. She was succeeded by her younger sister Margaret who died at the age of 80 in 1280, when her grandson, John II. of Avesnes, became count of Hainaut; Guy of Dampierre, her second son by her second marriage, became count of Flanders.

The government of Guy of Dampierre was unfortunate. It was the interest of the Flemish weavers to be on good terms with England, the wool-producing country, and Guy entered into an alliance with Edward I. against France. This led to an invasion and conquest of Flanders by Philip the Fair. Guy with his sons and the leading Flemish nobles were taken prisoners to Paris, and Flanders was ruled as a French dependency. But though in the principal towns, Ghent, Bruges and Ypres, there was a powerful French faction, the arbitrary rule of the French governor and officials stirred up the mass of the Flemish people to rebellion. The anti-French partisans were strongest at Bruges, where the French garrison was massacred (May 19, 1302), and on the following July 11 a French army of invasion was utterly defeated near Courtrai. Peace was concluded in 1305 but, owing to Guy of Dampierre and the leading Flemish nobles being in the hands of the French king, on terms very disadvantageous to Flanders. Very shortly afterwards the aged count Guy died. Robert of Bethune, his son and successor, had continual difficulties with France during the whole of his reign, the Flemings offering a stubborn resistance to all attempts to destroy their independence. Robert was succeeded in 1322 by his grandson Louis of Nevers, who had been brought up at the French court and had married Margaret of France. His sympathies were entirely French, and he made use of French help in his contests with the communes.

Under Louis of Nevers Flanders was practically reduced to the status of a French province. The latter part of his reign was remarkable for the successful revolt of the Flemish communes under Jacob van Artevelde (*q.v.*). Louis of Nevers fell at the battle of Crécy (1346), and was succeeded by his son Louis II. of Mâle. The reign of this count was one long struggle with the communes, headed by the towns of Ghent, for political supremacy. Louis was as strong in his French sympathies as his father, and relied upon French help in enforcing his will upon his refractory subjects. Had the great towns with their organized guilds and great wealth held together in their opposition to the count's despotism they would have proved successful; but Ghent and Bruges, always keen rivals, broke out into open feud. The power of Ghent reached its height under Philip van Artevelde (*q.v.*) in 1382. He defeated Louis, took Bruges and was made *ruward* of Flanders, but on Nov. 27, 1382, he suffered a crushing defeat from a large French army at Roosebeke and was slain. Louis of Mâle died two years later, leaving an only daughter Margaret, who had married in 1369 Philip the Bold, duke of Burgundy.

Subjection to Burgundy.—The history of Flanders as a separate State ceases from the time of the acquisition of the countship by the Burgundian dynasty (*see* BURGUNDY; NETHERLANDS). There were revolts from time to time of great towns against the exactions even of these powerful princes, but they were in vain. The conquest and humiliation of Bruges by Philip the Good in 1440, and the even more relentless punishment inflicted on rebellious Ghent by the emperor Charles V. exactly a century later are the most remarkable incidents in the long-continued but vain struggle of the Flemish communes to maintain and

assert their privileges. The Burgundian dukes and their successors of the house of Habsburg were fully alive to the value to them of Flanders and its rich commercial cities. It was Flanders that furnished to them no small part of their resources, but for this very reason, while fostering the development of Flemish industry and trade, they were the more determined to brook no opposition which sought to place restrictions upon their authority.

The effect of the revolt of the Netherlands and the War of Dutch Independence which followed was ruinous to Flanders. Albert and Isabel on their accession to the sovereignty of the southern Netherlands in 1599 found "the great cities of Flanders and Brabant had been abandoned by a large part of their inhabitants; agriculture hardly in a less degree than commerce and industry had been ruined." In 1633, with the death of Isabel, Flanders was restored to Spanish rule. Under the Treaty of Munster the north-western portion of Flanders, since known as States (or Dutch) Flanders, was ceded by Philip IV. to the United Provinces (1648). By a succession of later treaties—of the Pyrénées (1659), Aix-la-Chapelle (1668), Nijmegen (1679) and others—a large slice of the southern portion of the old county of Flanders became French territory and was known as French Flanders.

From 1795 to 1814 Flanders, with the rest of the Belgic provinces, was incorporated in France, and was divided into two departments—*département de l'Escaut* and *département de la Lys*. This division has since been retained, and is represented by the two provinces of East Flanders and West Flanders in the modern kingdom of Belgium. The title of count of Flanders was revived by Leopold I. in 1840 in favour of his second son, Philip Eugene Ferdinand (d. 1905). (G. E.)

FLANDRIN, JEAN HIPPOLYTE (1809-1864), French painter, was born at Lyons on March 24, 1809. His father, though brought up to business, had great fondness for art, and became a miniature painter. Hippolyte was the second of three sons, all painters, and two of them eminent, the third son Jean Paul (b. 1811) ranking as a leader of the modern landscape school of France. Auguste (1804-1842), the eldest, passed the greater part of his life as professor at Lyons. After studying for some time at Lyons, Hippolyte and Paul set out to walk to Paris in 1829. They entered the atelier of Ingres, who became their friend for life. At first considerably hampered by poverty, Hippolyte's difficulties were removed by his taking, in 1832, the Grand Prix de Rome for his picture, the "Recognition of Theseus by his Father." On his return from Rome his reputation was established. The works upon which his fame rests are his mural decorations. Of these the principal are in the following churches: St. Séverin, St. Vincent de Paul, St. Germain des Prés at Paris, St. Paul at Nîmes, the church of Ainay at Lyons. He died of smallpox at Rome on March 21, 1864. There is in his works much of that austerity and coldness which spring from a faith which feels in opposition to the surrounding life. He has been compared to Fra Angelico; but his saints and martyrs seem to express rather austerity of souls convicted of sin than the joy and purity which shine from the work of the early master. He was Ingres' most distinguished pupil, and followed in the paths of the Italian masters with little originality. Only a certain blonde, slightly melancholy face of a maiden is Flandrin's own peculiar interpretation; by transferring his pure principles to portrait painting he acquired a large practice as the painter of the "femme honnête" among the ladies of the Second Empire.

See Delaborde, *Lettres et Pensées de H. Flandrin* (1877); L. Flandrin, *H. Flandrin* (1903).

FLANNAN ISLANDS. A group of islands off the coast of the outer Hebrides. They are uninhabited.

FLANNEL. A woollen stuff of various degrees of weight and fineness, made usually from loosely spun yarn. The origin of the word is uncertain, but in the 16th century flannel was a well-known production of Wales, and a Welsh origin has been suggested. The French form *flanelle* was used late in the 17th century and the Ger. *Flanell* early in the 18th century. Baize, a kind of coarse flannel with a long nap, is said to have been first introduced to England about the middle of the 16th century by refugees from

France and the Netherlands. The manufacture of flannel has naturally undergone changes and, in some cases, deteriorations. Flannels are frequently made with an admixture of silk or cotton, and in low varieties cotton has tended to become the predominant factor. Formerly a short staple wool of fine quality from a South-down variety of the Sussex breed was principally in favour with the flannel manufacturers of Rochdale, who also used largely the wool from the Norfolk breed, a cross between the Southdown and Norfolk sheep. In Wales the short staple wool of the mountain sheep was used and in Ireland that of the Wicklow variety of the Cottagh breed, but now the New Zealand, Cape and South American wools are extensively employed and English wools are not commonly used alone. Over 2,000 persons are employed in flannel manufacture in Rochdale alone, which is the historic seat of the industry and a good deal of flannel is now made in the Spenn Valley district, Yorkshire. Blankets, which constitute a special branch of the flannel trade, are largely made at Bury in Lancashire and Dewsbury in Yorkshire. Welsh flannels have a high reputation, and make an important industry in Montgomeryshire. There are also flannel manufactories in Ireland.

A moderate export trade in flannel is done by Great Britain. The following table gives the quantities exported in 1924-27:

	sq.yds.		sq.yds.
1924	7,787,000	1926	4,427,900
1925	5,857,500	1927	5,545,900

FLANNELETTE, a descriptive term signifying a particular style of finishing and applied to an important class of cotton fabrics of simple texture, which have either one side only or, more usually, both sides formed with a short fleecy "nap" or fur. This nap is developed after weaving, by submitting the fabric to a finishing operation variously described as "teasling," "raising," or "perching," during which the fibrous filaments of cotton are scratched up and raised, thereby producing the short furry nap which is the distinctive characteristic of flannelette.

Flannelette is made in many different qualities ranging from comparatively coarse to fine textures that are used for a variety of domestic purposes, but mainly for clothing, and especially for undergarments and night attire, for which it is very suitable owing to its flannel-like and woolly character which imparts to the body a feeling of comfort and warmth. This attribute of flannelette results, of course, more especially from the presence of air in the short nap, which, being a poor conductor of heat, serves the more effectively to insulate the body, and thus prevents the radiation of heat, after the manner of the furry coats of animals.

It is this aerated property of flannelette which increases its susceptibility to ignition, for until the nap is formed on the surface it is no more inflammable than any other type of fabric, whether produced from cotton or other textile material. Flannelette does not possess the inherent properties of highly inflammable volatile and ethereal fluids of an explosive character, which are liable to ignition by a flame at some distance. Unless it comes into actual contact with fire, it is as immune from the risk of ignition as fabrics of any other textile material. Garments made of flannelette are in universal use, especially as night attire for children, who are often foolishly allowed to crouch near the fire to warm themselves just before going to bed, or to retire to bed carrying a lighted lamp or candle. These are the occasions when flannelette becomes a dangerous material, and herein lies the only risk of its use, not in any inherent property of inflammability. Indeed, it is highly probable that by providing a cheaper material for warm clothing, flannelette has saved infinitely more lives than it has destroyed. Nevertheless, so strong is the prejudice of many people against the risk of fire incurred by using flannelette that it is, in some cases, submitted to chemical treatment in order to render it harmless. The additional cost of that process, however, is such as to prevent its becoming a commercial success.

There is no feature of special technical interest attaching to the manufacture of flannelettes, which are usually based on plain calico, three-end 1x2 twill, four-end 2x2 twill, or a similar weave structure, calculated to produce a relatively close and firm texture, free from long "floating" threads that would be liable to break during the operation of raising the nap. Also, since the nap

is formed by raising the fibres composing the weft yarn, this is spun "soft," with less twist and of coarser counts than the warp yarn, which requires to be stronger than the weft.

Flannelettes are produced in a variety of different styles, as "plain," striped, checked, and sometimes printed with simple diapered figuring. The plain fabrics are usually woven in the "grey" state, or natural colour of cotton, and afterwards piecedyed, or else bleached; while the stripes and check patterns are developed by employing threads of coloured warp and weft.

(H. N.)

FLARE. The term flare in pyrotechny is applied either to coloured fire composition burnt in a loose heap, or to a similar composition charged into a rolled paper case, thus ensuring longer and more regular burning. Flares are used in pyrotechnic displays for the illumination of the surroundings and in a suitable setting, such as a background of trees and foliage, rocks or old buildings. With expert arrangement most beautiful effects are to be achieved, particularly where flares charged with varying composition are used, producing changing and blending colouring.

The flare, or light, in its present form can claim no greater antiquity than the early part of last century, when the introduction of chlorate of potash permitted the development of genuine colour composition. (See FIREWORKS: *Coloured Fire*.) Previous to this the only colour achieved, in addition to flame colour, had been the bluish-white light produced by a mixture of sulphur, saltpetre and orpiment. These blue lights, as they were called, were and still are much used at sea for signalling and illuminating purposes. They were also known as Bengal lights, no doubt because Bengal was the chief source of supply of saltpetre.

Signal Flares and Lights.—The introduction of colours which could readily be recognized at a considerable distance opened up a much wider field for the use of flares at sea, and from the middle of the 19th century many patents were taken out; most of these had for their object a means of self ignition. The first of these inventions was that of Robson, who ignited the flare by breaking a small hollow bead containing sulphuric acid which came into contact with a pellet of chlorate of potash. Subsequent inventions provided for ignition on the same principle as the modern safety match, and for the waterproofing of the surface, enabling the flare to be ignited in rough weather. Lights of this kind are generally fitted with a wooden handle, in, or to which is secured the means of ignition. The use of pyrotechnic signals for recognition purposes at sea suggested the Coston light, patented in 1859—a flare charged with layers of composition of varying colours. An invention which has proved of great value at sea is the Holmes light, a device by which a lifebuoy fitted with a flare is automatically launched and the flare ignited on the alarm being given.

The introduction of wireless telegraphy has, to a great extent, rendered recognition signals obsolete, but large quantities of flares are still used by the fishing fleets and by the lifeboat and coast-guard services. Ships' lifeboats are compelled to carry a supply of red friction ignition lights by British Board of Trade regulations.

During the World War flares and lights of many kinds were designed for signalling and illuminating purposes, the largest ever made being the Dover flares, designed by the late Wing-commander Brock, for use on the anti-submarine defences in the English channel, the complete flare being 3ft. in length, 8in. in diameter and weighing 90 lb., giving a light estimated at one million candle power. The smallest is that fired from a pistol by the infantryman to illuminate the ground in front. (A. St. H. B.)

FLASH POINT: see ABEL TEST.

FLASK, in its earliest meaning, a vessel, made of wood or leather, for carrying liquor. The principal applications in current usage are (1) to a vessel of metal or wood, formerly of horn,

used for carrying gunpowder; (2) to a long-necked, round-bodied glass vessel, usually covered with plaited straw or maize leaves, containing olive or other oil or Italian wines—it is often known as a "Florence flask"; (3) to similarly shaped vessels, used for experiments, etc., in a laboratory; (4) to a small metal or glass receptacle for liquor, of a size and shape to fit into a pocket or holster, usually covered with leather, basket-work or other protecting substance, and with a detachable portion of the case shaped to form a cup. "Flask" is also used in metal-founding; it is a wooden frame or case to contain part of the mould. The word "flagon," which is by derivation a doublet of "flask," is usually applied to a larger type of vessel for holding liquor, more particularly to a type of wine-bottle with a short neck and circular body with flattened sides. The term is also used for a jug-shaped vessel with a handle, spout and lid, into which wine may be decanted from the bottle for use at table, and of a similarly shaped vessel to contain the eucharistic wine till it is poured into the chalice. (See DRINKING VESSELS.)

FLAT. The word is generally applied by British usage to a self-contained residence or separate dwelling (in Scots law, the term *flatted house* is still used), consisting of a suite of rooms which form a portion, usually on a single floor, of a large building, called the tenement house, the remainder being similarly divided. The approach to it is over a hall, passage and stairway, which are common to all residents in the building, but from which each private flat is divided off by its own outer door.

There is in England a considerable body of special law applicable to flats. The following points deserve notice:—(1) The occupants of distinct suites of rooms in a building divided into flats are generally, and subject, of course, to any special terms in their agreements, not lodgers but tenants with exclusive possession of separate dwelling houses placed one above the other. Apart from statute, they are therefore, liable to distress by the immediate landlord. The protection given to tenants by the Rent Restriction Act, 1920–25 (see LANDLORD AND TENANT; RENT), extends, however, to flats other than those let at a rent including payments which are not of an unsubstantial or trivial character, for board, or as in the case of service flats, attendance or use of furniture (Act of 1920 s.12). Each flat is separately rateable, though as a general rule by the contract of tenancy the rates are payable by the landlord. (2) The owner of an upper storey, without any express grant or enjoyment for any given time, has a right to the support of the lower storey (*Dalton v. Angus*, 1881, 6 A.C. 740, 793). The owner of the lower storey, however, so long as he does nothing actively in the way of withdrawing its support, is not bound to repair, in the absence of a special covenant imposing that obligation upon him. The right of support being an easement in favour of the owner of the upper storey, it is for him to repair. He is in law entitled to enter on the lower storey for the purpose of doing the necessary repairs. The duty of the landlord, who retains control and possession of a common staircase, is a common-law duty, and it cannot be put higher than this: that he is bound to maintain it under such a condition that those who are invited to use it will not be exposed to any dangers which cannot be avoided by the exercise of ordinary care. (*Fairman v. Perpetual Investment Building Society*, 1923 A.C. 74, 98, and see *Letang v. Ottawa Electric Ry. Co.*, 1926, A.C. 725). (3) In case of the destruction of the flat by fire, the rent abates *pro tanto* and an apportionment is made; *pari ratione*, where a flat is totally destroyed, the rent abates altogether, unless the tenant has entered into an express and unqualified agreement to pay rent, when he will remain liable till the expiration of his tenancy. (4) Where the agreements for letting the flats in a single building are in common form, an agreement by the lessor not to depart from the kind of building there indicated may be held to be implied. (5) The porter is usually appointed and paid by the landlord, who is liable for his acts while engaged on his general duties; while engaged on any special duty for any tenant the porter is the servant of the latter, who is liable for his conduct within the scope of his employment. (See also HOUSING.)

In Scots law the rights and obligations of the lessors and lessees of flats, or—as they are called—"flatted houses," spring

FRICTION IGNITION FLARE
This is fired by withdrawing the plug from the handle and drawing the end across the surface of the exposed ignition composition

partly from the exclusive possession by each lessee of his own flat, partly from the common interest of all in the tenement as a whole. The "law of the tenement" may be thus summed up. The *solum* on which the flatted house stands, the area in front and the back ground are presumed to belong to the owner of the lowest floor or the owners of each floor severally, subject to the common right of the other proprietors to prevent injury to their flats, especially by depriving them of light. The external walls belong to each owner in so far as they enclose his flat; but the other owners can prevent operations on them which would endanger the security of the building. The roof and uppermost storey belong to the highest owner or owners, but he or they may be compelled to keep them in repair and to refrain from injuring them. The gables are common to the owner of each flat, so far as they bound his property, and to the owner of the adjoining house; but he and the other owners in the building have cross rights of common interest to prevent injury to the stability of the building. The floor and ceiling of each flat are divided in ownership by an ideal line drawn through the middle of the joists; they may be used for ordinary purposes, but may not be weakened or exposed to unusual risk from fire. The common passages and stairs are the common property of all to whose premises they form an access, and the walls which bound them are the common property of those persons and of the owners on their farther side.

The French Code Civil provides (art. 664) that where the different storeys of a house belong to different owners the main walls and roof are at the charge of all the owners, each one in proportion to the value of the storey belonging to him. The proprietor of each storey is responsible for his own flooring. The proprietor of the first storey makes the staircase which leads to it, the proprietor of the second, beginning from where the former ended, makes the staircase leading to his, and so on. There are similar provisions in the Civil Codes of Italy (art. 562); Spain (art. 396); Portugal (art. 2335); Quebec (art. 521); and St. Lucia (art. 471). As to Belgium, see law of July 8, 1924.

In the United States the term flat has given way in use to "apartment house" and, in the congested city districts housing the poor, to "tenements." The States having cities of sufficient size to justify the construction of apartment houses have special legislation on the subject similar to that in England.

The term *flat* is used in the United States to describe a sale of bonds in which the price paid covers the bond itself and all accrued interest thereon. Bonds are not usually sold *flat*, but rather at a given price plus accrued interest. Stocks, on the contrary, are usually sold *flat*; i.e., the purchase price entitles the buyer not only to the ownership of the stock but also to all dividends which may be forthcoming upon it. (See ACCRUED INTEREST.)

Flat, in music, is the sign *b*, signifying the lowering of the note to which it is attached by a semitone, the direction holding good to the end of the bar. Or, if placed at the beginning of the stave, as part of what is called the key signature, it governs the note concerned throughout the composition unless contradicted. A double flat (*bb*) lowers a note two semitones. (See ACCIDENTALS; CLEF; MUSICAL NOTATION.)

FLATBUSH, formerly a township of Kings county, Long Island, N.Y.; since 1898 a part of the borough of Brooklyn, New York city. The first settlement was made here by the Dutch about 1651, and was variously called "Midwout," "Midwoud" and "Medwoud" (from the Dutch words, *med*, "middle" and *woud*, "wood") for about 20 years, when it became more commonly known as *Vlachte Bos* (*vlachte*, "wooded"; *bos*, "plain") or *Flackebos*, whence, by further corruption, the present name. On Aug. 23, 1776, the village was occupied by Cornwallis's division of the invading force under Lord Howe, and on the 27th, at the disastrous battle of Long Island (or "battle of Flatbush," as it is sometimes

called), Flatbush pass, an important strategic point, was vigorously defended by Sullivan's troops.

FLAT-FISH is the name of the fishes of the order *Heterosomata*, which differ from all other fishes in having both eyes on one side. They live at the bottom, with the eyed side uppermost; this is coloured, whereas the blind or underside is normally white; but exposure of this side to light will cause some development of pigment. Nearly all flat-fishes are marine, and they have minute floating eggs; the larvae are symmetrical, with an eye on each side, and swim near the surface of the sea; but after a time one eye moves round over the top of the head to the other side and the little fish, falling over gradually on its side, sinks to the bottom. In all but the primitive *Psettodes* the dorsal fin grows forward on to the head and in some with a long larval life this happens before the eye migrates, so that in pushing its way between the fin and the head it seems to go through the head from one side to the other. Many flat fishes are remarkable for their power of changing their coloration in order to resemble the ground on which they lie, and it has been established by experiment that they must see the ground in order to look like it. The eyes do not look upwards, but in life stand out from the head and can be turned independently in different directions looking sideways, or sometimes one forward and the other backward.

Psettodes.—The most primitive genus, with two species, from West Africa and the Indo-Pacific, is typically perch-like in structure, and indicates the derivation of flat-fishes from some pescoid ancestor allied to the *Senanidae* or sea-perches. The other flat-fishes, numbering about 600 species, are either flounders, with the lower jaw prominent, or soles, in which the rounded snout projects beyond the small curved mouth; each of these groups includes a family with the eyes on the right side, and another with the eyes on the left. The *Pleuronectidae*, or dextral flounders, include the halibut, plaice and other important food-fishes of northern seas. The *Bothidae*, or sinistral flounders, include the turbot; some of the American species of *Paralichthys* are also valued as food. The *Soleidae*, or true soles, with eyes on the right side include the well known common sole of Europe. The *Cynoglossidae*, or tongue-soles, with eyes on the left side, inhabit tropical and subtropical waters.

In the more specialized forms, which feed exclusively on bottom-living invertebrates, the jaws of the blind side are more strongly developed than those of the eyed side, and have stronger teeth; in the soles those of the eyed side are toothless.

FLATHEAD. This name has been applied to a variety of tribes in north-western and south-eastern North America who practised frontal and occipital compression of infants' heads, resulting in permanent deformation of the skull, especially a low forehead and posterior breadth. The process was not injurious, did not affect intelligence, and like other habitually practised deformations and mutilations the world over, was looked upon as correct and beautifying. The effects of course were not inherited. In modern official and popular usage in the United States, Flathead is the designation of the Salst or Salish, the eponymous tribe of the Salish stock (*q.v.*), in western Montana, numbering 600, about the same as in 1805. (A. L. K.)

BY COURTESY OF THE SMITHSONIAN INSTITUTION

FLATHEAD INDIAN BRAVE

FLATMAN, THOMAS (1637-1688), poet and miniature painter, was educated at Winchester (1649-54) and New college, Oxford (1654-56). He left Oxford without a degree in 1657, having been made fellow of his college in the previous year. In 1666 he was created M.A. of Cambridge by the king's letters. As a miniature painter he is highly esteemed by modern critics, but only a few of his poems have survived in anthologies. He died in London, on Dec. 8, 1688. His collected works first appeared in 1674, as *Poems and Songs*, and an enlarged edition in 1686; many of his verses, however, were printed separately,

the most notable being "A Thought of Death" (imitated by Pope); "Death, a Song"; and "Hymn for Morning." *Montélión's Almanack* for 1661 and 1662 and a mock romance, *Don Juan Lambeiro*, have also been ascribed to Flatman, by Wood.

See Anthony à Wood, *Athenae Oxonienses*, vol. iv. (edit. P. Bliss, 4 vols., 1813-20); H. Walpole, *Anecdotes of Painting* (1762-71, later ed. 1879); S. Redgrave, *Dictionary of Artists* (new ed. rev. 1878); also F. A. Child, *Life and Uncollected Poems of T. Flatman* (Philadelphia, 1921).

FLATWORM, a general name for members of the phylum Platyhelminthes (*q.v.*), including the flukes (see TREMATODES), tapeworms (*q.v.*) and certain free-living forms. (See TURBELLARIA.)

FLAUBERT, GUSTAVE (1821-1880), French novelist, was born at Rouen on Dec. 12, 1821. His father was resident physician at the Rouen hospital; his mother belonged to an old Norman family. He was educated in his native city, and went up to Paris to study law in 1840. He took no great interest in his legal studies. From early childhood he had been writing, and he continued to write in Paris. The two great friends of his Rouen schooldays, Chevalier and Le Poittevin, were fellow-students in Paris, and in Pradier's studio he met Victor Hugo, Louise Colet, Maxime du Camp and other figures in Paris literary society. At this time he began to suffer from the attacks of a malady (not epilepsy, as is sometimes stated), which recurred throughout his life, and his father recalled him to Rouen in order to give him the necessary care. A journey with his family to Italy seems to have given him little pleasure. Change of scene was more fruitful in retrospect than at the time. When he was abroad Flaubert felt homesick for Normandy; in Normandy he dreamed of the East. His real life, as he told his friend Le Poittevin, was "dans l'idée et pas ailleurs."

In 1846, after the deaths of his father and of his sister Caroline, to whom he had been devotedly attached, Flaubert settled with his mother at Croisset, near Rouen, in the pleasant house with grounds going down to the Seine, which is familiar from his correspondence. It was his home for the rest of his life, and he rarely left it except for occasional visits to Paris. At this time began his only serious *liaison*, that with Louise Colet (*q.v.*), whom he visited from time to time, and with whom he carried on an almost daily correspondence, which has been published, unfortunately only in an incomplete form. The relation lasted until 1855. It had not been entirely peaceful, and the breach, when it came, was a violent one. Louise asked of him more than he was willing to give. He was absorbed in *Madame Bovary*, who was Louise's real supplanter. His friends throughout this period were Louis Bouilhet (*q.v.*), like himself a native of Rouen, with whom he regularly discussed his work, and Maxime du Camp. Du Camp did not like Louise, and the fact may unconsciously have influenced Flaubert in the final breach. With du Camp he travelled in Brittany in 1847, and in 1849 the two friends set out for the Mediterranean. During this tour in the Levant the history of *Madame Bovary* seems to have taken shape. He had already written an *Education sentimentale*—indeed two, between 1843 and 1845, and a *Tentation de Saint Antoine* in 1848-49, neither of which saw the light. Later on he was to take up these subjects again. He began his studies for the *Tentation* in 1846, and spent the months between May 1848 and Sept. 1849 in writing it. He read the completed ms. to Bouilhet and Du Camp. Bouilhet found it too diffuse, and declared that Flaubert should write the story of Delamarre, a country doctor who had been driven to suicide by the infidelity of his wife. The *Tentation* was put aside, in deference to Bouilhet's opinion, and the way left clear for *Madame Bovary*. The actual writing of the book occupied more than four years, from the beginning of 1852 to May 1856. Up to the time of his breach with Louise Colet the progress of the work is registered in his letters to her. He despatched the manuscript in May, and in October it began to appear in the *Revue de Paris*. It was to be the centre of discussion on the art of the novel for years to come; every critic finds a new aspect in *Madame Bovary*, and it has been and is made to illustrate the most diverse literary doctrines. For the moment attention was focussed on the subject and its treatment, not on the writer's art, for the Government brought a charge of

immorality against author and publisher. Both were acquitted, and the novel appeared in book form in 1857. Meanwhile he returned from time to time to the *Tentation*, but the scandal following the publication of *Madame Bovary* made him decide to lay it aside.

Flaubert's mind was already at work on *Salammô*. On its appearance in 1862 the critics fell foul of it, but the young generation read it with enthusiasm. The war of the mercenaries against Carthage was a great subject, greatly handled. From Carthage he turned again to contemporary life, and produced, after seven years' work, the final version of *L'Education sentimentale* (1869). Criticism was on the whole unfavourable, though some good judges, among them Metternich, recognized the justness and the greatness of this picture of the generation of 1840 to 1850.

Up to this time the sequestered and laborious life of Flaubert had been comparatively happy, but misfortunes began to gather around him. He felt the anguish of the war of 1870 so keenly that the break-up of his health has been attributed to it; he began to suffer more from his distressing nervous malady. His best friends were taken from him by death or by fatal misunderstanding; in 1872 he lost his mother, and his circumstances were reduced. He was very tenderly guarded by his niece; he enjoyed a rare intimacy of friendship with George Sand, with whom he carried on a correspondence which is supremely interesting both from the human and the artistic point of view; and occasionally he saw his Parisian acquaintances, Zola, A. Daudet, Turgenev, the Goncourts; but the later years of Flaubert's life were desolate and melancholy. He continued to work with the same intensity. *La Tentation de Saint-Antoine*, of which fragments had been published as early as 1857, was at length completed and sent to press in 1874. His drama *Le Candidat*, which was produced in that year, was a failure. In 1877 Flaubert published, in one volume, entitled *Trois Contes*, "Un Coeur Simple," "La Légende de Saint-Julien-l'Hospitalier" and "Hérodias." Those who were dismayed by the solidity of *L'Education sentimentale*, appreciated these short and perfect pieces. They place him among the great masters of the short story, and all later writers in this *genre*, from Maupassant onwards, stand in debt to Flaubert. He spent the remainder of his life in the toil of building up a vast satire on the futility of human knowledge and the omnipresence of mediocrity, which he left a fragment. This is *Bouvard et Pécuchet* (posthumously printed, 1881), which he himself believed to be his masterpiece. This is not the general view, but this gigantic attack on optimism has its enthusiasts; Rémy de Gourmont agreed with Flaubert. Flaubert had rapidly and prematurely aged since 1870, and he was quite an old man when he died of apoplexy on May 8, 1880. He died at Croisset, but was buried in the family vault in the cemetery of Rouen. A beautiful monument to him by Chapu was unveiled at the museum of Rouen in 1890.

Flaubert had the build of a guardsman, with a magnificent viking head, but his health was uncertain from childhood, and he was neurotic to the last degree. His hatred of the "bourgeois" began in his childhood, and developed into a kind of monomania. He despised their habits, their lack of intelligence, their contempt for beauty, with a passionate scorn which has been compared to that of an ascetic monk. His laborious methods of work have become a legend. He would spend a week in the completion of one page, never satisfied till he had found the best turn of a phrase, the final adjective. That he was one of the greatest French writers of his century is now recognized. Less perhaps than any other writer, not of France, but of modern Europe, Flaubert yields admission to the inexact, the abstract, the vaguely inapt expression. He never allowed a *cliché* to pass him, never indulgently or wearily went on, leaving behind him a phrase which "almost" expressed his meaning. He hated the lax felicities of improvisation as a disloyalty to his art. The absolute exactitude with which he adapts his expression to his purpose is seen in all parts of his work, but particularly in the portraits he draws of the figures in his principal romances.

The degree and manner in which, since his death, the fame of Flaubert has extended, form an interesting chapter of literary history. The publication of *Madame Bovary* in 1857 had been

followed by more scandal than admiration; it was not understood at first that this novel was the beginning of a new thing, the scrupulously truthful portraiture of life. Gradually this aspect of his genius was accepted, and began to crowd out all others. At the time of his death he was famous as a realist, pure and simple. Under this aspect Flaubert exercised an extraordinary influence over E. de Goncourt, Alphonse Daudet and Zola. But even since the decline of the realistic school other facets of his genius have caught the light. It has been perceived that he was not merely realistic, but real; that his clairvoyance was almost boundless; that the significance of his character is the significance only attained by the great masters. It was not for nothing that he studied increasingly *Don Quixote*. Flaubert was a dreamer and a symbolist as well as a realist. The creator of Saint Antoine and Hérodiade exercised as important an influence on the symbolists as the creator of *Madame Bovary* on the realists. The dualism which he describes in his own character of the two Flauberts, the one loving lyricism and "eagle flights," the other digging for facts and desiring to present with equal precision and detail the smallest as well as the greatest of the things he describes, is apparent in his works. This is one of the reasons why the work of Flaubert is of inexhaustible interest to thinkers and writers of all temperaments.

His *Oeuvres complètes* (8 vols., 1885) were printed from the original mss., and included, besides the works mentioned already, the two plays *Le Candidat* and *Le Château des Coeurs*. Earlier editions of his works are practically superseded by the Conard edition of 1910 (18 vols.), which includes *Madame Bovary*, *Salammô*, *Notes de Voyages*, *Trois Contes*, *Correspondance*, the three texts of *La Tentation de Saint Antoine* (1849, 1856 and 1874), and two versions of *L'Éducation sentimentale* (1845 and 1880). A complete edition was also published by Charpentier in 1914 (13 vols.).

Coleman, *Flaubert's Literary Development* (1914); E. Maynial, *La Jeunesse de Flaubert* (1913) and *Flaubert et son milieu* (1927); A. Thibaudet, *Gustave Flaubert, 1821-1880* (1922); L. Degoumois, *Flaubert à l'École de Goethe* (1925).

FLAVIAN, SAINT (d. 449), bishop of Constantinople and an adherent of the Antiochene school, succeeded Proclus in 447. He presided at the council which deposed Eutyches (q.v.) in 448, but in the following year he was deposed by the council of Ephesus (the "robber synod"), which reinstated Eutyches. Flavian's death was attributed to ill treatment at the hands of his theological opponents. The council of Chalcedon (451) canonized him as a martyr, and in the Latin Church he is commemorated on Feb. 18.

Three of Flavian's letters are preserved in Migne, *Patr. Lat.* 54 and *Patr. Graec.* 65. His appeal to Pope Leo I. against the council of Ephesus was edited by Lacey (Cambridge, 1903).

FLAVIAN I. (c. 320-c. 404), bishop or patriarch of Antioch, was probably born in Antioch. He supported the Catholic faith against the Arian Leontius, who had succeeded Eustathius as bishop of Antioch. When Meletius was appointed bishop of Antioch in 361 he raised Flavian to the priesthood, and on the death of Meletius in 381 Flavian was chosen to succeed him. The bishop of Rome and the bishops of Egypt refused to acknowledge Flavian, and Paulinus, who by the extreme Eustathians had been elected bishop in opposition to Meletius, still exercised authority over a portion of the church. On the death of Paulinus in 383, Evagrius was chosen as his successor, but after the death of Evagrius (c. 393) Flavian succeeded in preventing his being followed by a successor, though the Eustathians still continued to hold separate meetings. Through the influence of Chrysostom and of the emperor Theodosius, Flavian was acknowledged in 399 as legitimate bishop of Antioch by the Church of Rome; but the Eustathian schism was not healed till 415. The Greek Church commemorates him on Sept. 26.

See MELETIUS OF ANTIOCH, and Herzog-Hauck's *Realencyklop.*

FLAVIAN II. (d. 518), bishop or patriarch of Antioch, was chosen by the emperor Anastasius I. to succeed Palladius, most probably in 498. He endeavoured to please both parties by a middle course in reference to the Chalcedon (q.v.) decrees, but after great hesitation accepted the Henoticon, or decree of union, issued by the emperor Zeno. This brought upon him the anathema of the patriarch of Constantinople, and failed to secure the favour

of Anastasius, who found in the riots between the rival parties in 511 a pretext for banishing Flavian to Petra, where he died.

FLAVIGNY, a town of eastern France, in the department of Côte-d'Or, stands on a hill above the river Ozerain, 33 m. W.N.W. of Dijon by road. Pop. (1926) 559. The 8th century abbey has been rebuilt as a factory for the manufacture of anise, an industry connected with the town as early as the 17th century. There are also a church of the 13th and 15th centuries, and ancient gateways. About 3 m. N.W. of Flavigny rises Mont Auxois, the site of the ancient Alesia, where Caesar in A.D. 52 defeated the Gallic chieftain Vercingetorix, to whom a statue has been erected on the top of the hill. Many finds of the Gallo-Roman period have been made on the hill.

FLAVIN, the commercial name for an extract or preparation of quercitron bark (q.v.), which is used as a yellow dye in place of the ground and powdered bark.

FLAVIUS, BLONDUS (c. 1388-1463), Italian historian, was born at Forlì. After acting as ambassador to Milan, he was exiled to Venice from 1423-32, when he became secretary to Pope Eugene IV. He died in Rome in 1463.

His collected works, including the *Romae instauratae, lib. iii.*, *Romae triumphantis lib. x.*, *Italia illustrata, Decades* and *De origine et gestis Venetorum*, were often printed in the 16th century, notably at Basle in 1531. B. Nogara has edited *Scritti inediti e rari di B. Flavio* in "Studi e Testi" series, no. 48 (1927).

FLAVOURINGS. Flavouring agents, with the exception of common salt, are obtained from vegetables and may be from any part of the plant, that is, leaf, stem, root or fruit. Though useful in helping to make certain foods palatable and hence easier to digest, condiments have no food value and should be regarded purely as food "accessories." Flavourings should always be blended with food in cooking and not served with the food. This rule should apply to salt and pepper but custom has largely prevailed to the contrary in this case. All condiments ought to be used sparingly and in such proportions that they do not spoil the natural flavours of the other ingredients.

Pot Herbs.—This expression is usually applied to a particular set of flavouring herbs (parsley, thyme, bay leaf and marjoram) which are used in the form of a "bouquet" for stews, sauces, etc. A complete bouquet has other flavourings added such as lemon, celery, mace, tarragon, etc. The term "pot herbs" is also familiarly given to onion, carrot and turnip added to stock.

Essences.—These are made by immersing a flavouring agent (e.g., celery seed) in spirits of wine for several days to form a tincture; or, an essential oil, obtainable at a pharmacy (e.g., oil of bitter almonds) is added to spirits of wine when the natural volatile oil cannot be obtained by ordinary methods of immersion and soaking. Examples of essences are cinnamon, nutmeg, lemon, ginger, etc. Vinegars are made by soaking some strong flavouring agent (e.g., chilli) in ordinary vinegar.

Other Condiments.—Fresh herbs or those dried in leaf or powdered are used in making sauces, stews, etc. It is usual to classify them according to the part of plant to which they belong: (a) Leaves and stems. Among these are sage (for flavouring forcemeats, etc.); spearmint, commonly alluded to as "mint" and used in making mint sauce for mutton; bayleaf (bouquets); marjoram, thyme and sweet basil (bouquets); parsley, used as garnish as well as a popular flavouring agent; peppermint, principally used in confectionery. (b) Flowers and buds. Cloves; saffron (used chiefly for colour); capers (pickles, sauces, etc.). (c) Barks. Cinnamon. (d) Roots. Horseradish (grated in sauce or eaten *au naturel* with beef; turmeric (chiefly for colour and as an ingredient in curry preparations); ginger (puddings, cordials and jams); garlic (stews and sauces); these are the best known. (e) Seeds. Aniseed (pastry, cakes, cordial); caraway (cakes); fennel (cakes and liqueurs); mustard; nutmeg and mace; cumin; coriander and various seeds used in curry preparations. (f) Fruits. In this class are certain immature fruits, such as all-spice, capsicum and vanilla pods, etc. See SAUCES.

FLAX. The terms flax and lint are employed at once to denote the fibre so called, and the plant from which it is prepared. The flax plant (*Linum usitatissimum*) belongs to the natural order *Linaceae*, and, like most plants which have been long under cultiva-

tion, it possesses numerous varieties, while its origin is doubtful. As cultivated it is an annual with an erect stalk rising to a height of from 20 to 40 in., with alternate, sessile, narrowly lance-shaped leaves, branching only at the top, each branch or branchlet ending in a bright blue flower. The flowers are regular and symmetrical, having five sepals, tapering to a point and hairy on the margin, five petals which speedily fall, ten stamens, and a pistil bearing five distinct styles. The fruit or boll is round, containing five cells, each of which is again divided into two, thus forming ten divisions, each of which contains a single seed. The seeds of the flat plant, well known as linseed, are heavy, smooth, glossy and of a bright greenish-brown colour. They are oval in section, but their maximum contour represents closely that of a pear with the stalk removed. The contents are of an oily nature, and when liquefied are of great commercial value.

Development of Flax Culture.—The earliest cultivated flax was *Linum angustifolium*, a smaller plant with fewer and narrower leaves than *L. usitatissimum*, and usually perennial. This is known to have been cultivated by the inhabitants of the Swiss lake-dwellings, and is found wild in south and west Europe (including England), North Africa, and Western Asia. The annual flax (*L. usitatissimum*) has been cultivated for at least four or five thousand years in Mesopotamia, Assyria and Egypt, and is wild in the districts included between the Persian gulf, the Caspian sea and the Black sea. This annual flax appears to have been introduced into the north of Europe by the Finns, afterwards into the west of Europe by the western Aryans, and perhaps here and there by the Phœnicians; lastly, into Hindustan by the eastern Aryans after their separation from the European Aryans. (De Candolle, *Origin of Cultivated Plants*.)

The cultivation and preparation of flax are among the most ancient of all textile industries, very distinct traces of their existence during the stone age being preserved to the present day. "The use of flax," says Ferdinand Keller (*Lake Dwellings of Switzerland*, translated by J. E. Lee), "reaches back to the very earliest periods of civilization, and it was most extensively and variously applied in the lake-dwellings, even in those of the stone period. But of the mode in which it was planted, steeped, heckled, cleansed and generally prepared for use, we can form no idea any more that we can of the mode or tools employed by the settlers in its cultivation. . . . Rough or unworked flax is found in the lake-dwellings made into bundles, or what are technically called heads, and, as much attention was given to this last operation, it was perfectly clean and ready for use." As to its applications at this early period Keller remarks: "Flax was the material for making lines and nets for fishing and catching wild animals, cords for carrying the earthenware vessels and other heavy objects; in fact, one can hardly imagine how navigation could be carried on, or the lake-dwellings themselves be erected, without the use of ropes and cords; and the erection of memorial stones (menhirs, dolmens), at whichever era, and to whatever people these monuments may belong, would be altogether impracticable without the use of strong ropes."

Flax Manufacture.—That flax was extensively cultivated and was regarded as of much importance at a very early period in the world's history there is abundant testimony. Especially in ancient Egypt the fibre occupied a most important place, linen having been there not only generally worn by all classes, but it was the only material the priestly order was permitted to wear, while it was most extensively used as wrappings for embalmed bodies and for

BY PERMISSION OF DR. EUGEN KÖHLER, "MEDIZINALE PFLANZEN"
FLAX (*LINUM USITATISSIMUM*) FROM WHICH LINEN IS MADE. ANCIENTLY CULTIVATED FOR ITS VALUABLE FIBRE

general purposes. In the Old Testament we are told that Pharaoh arrayed Joseph "in vestures of fine linen" (Gen. xlii. 42), and among the plagues of Egypt that of hail destroyed the flax and barley crops, "for the barley was in the ear, and the flax was balled" (Exod. ix. 31). Further, numerous pictorial representations of flax culture and preparation exist to the present day on the walls of tombs and in Egypt. Sir J. G. Wilkinson in his description of ancient Egypt shows clearly the great antiquity of the ordinary processes of preparing flax. "At Beni Hassan," he says, "the mode of cultivating the plant, in the same square beds now met with throughout Egypt (much resembling our salt pans), the process of beating the stalks and making them into ropes, and the manufacture of a piece of cloth are distinctly pointed out." The preparation of the fibre as conducted in Egypt is illustrated by Pliny (*q.v.*), who says: "The stalks themselves are immersed in water, warmed by the heat of the sun, and are kept down by weights placed upon them, for nothing is lighter than flax. The membrane, or rind, becoming loose is a sign of their being sufficiently macerated. They are then taken out and repeatedly turned over in the sun until perfectly dried, and afterwards beaten by mallets on stone slabs. That which is nearest the rind is called *stupa* ("tow"), inferior to the inner fibres, and fit only for the wicks of lamps. It is combed out with iron hooks until the rind is all removed. The inner part is of a whiter and finer quality. Men are not ashamed to prepare it" (Pliny. *N.H.* xix. 1). For many ages, even down to the early part of the 14th century, Egyptian flax occupied the foremost place in the commercial world, being sent into all regions with which open intercourse was maintained. Among Western nations it was, without any competitor, the most important of all vegetable fibres till towards the close of the 18th century, when, after a brief struggle, cotton took its place as the supreme vegetable fibre of commerce.

Cultivation of Land.—Flax prospers most when grown upon land of firm texture resting upon a moist subsoil. It does well to succeed oats or potatoes, as it requires the soil to be in fresh condition without being too rich. Lands newly broken up from pasture suit it well, as these are generally freer from weeds than those that have been long under tillage. The land, having been ploughed in autumn, is prepared for sowing by working it with the grubber, harrow and roller, until a fine tilth is obtained. On the smooth surface, when the plants are intended for fibre, the seed is sown broadcast by hand or machine, at the rate of three bushels per acre, in order that the plants may be rank, and thus prevent branching especially from the lower parts. It is advisable immediately to hand-rake it with common hay-rakes, and thus to remove all stones and clods, and to secure a uniform close cover of plants. When these are about 2 to 3 in. long the crop must be carefully hand-weeded. This is a tedious and expensive process, and hence the importance of sowing the crop on land as free as possible from weeds of all kinds. The weeders, faces to the wind, if any, move slowly on hands and knees, and should remove every vestige of weed in order that the flax plants may receive the full benefit of the land. The time of weeding should be chosen when the ground is damp. When flax is cultivated primarily on account of the fibre, the crop ought to be pulled before the capsules are quite ripe, when they are just beginning to change from a green to a pale-brown colour, and when the stalks of the plant have become yellow throughout about two-thirds of their height.

The various operations through which the crop passes from this point till flax ready for the market is produced are (1) Pulling, (2) Rippling, (3) Retting, (4) Drying, (5) Rolling, (6) Scutching.

Pulling and Rippling.—*Pulling* and *rippling* may be dismissed very briefly. Flax is always pulled up by the root, except in some parts of America and Canada where the plants are grown solely for seed. It is usually pulled by hand, but recently mechanical flax pulling machines have been introduced. The pulling ought to be done in dry clear weather; and care is to be taken in this, as in all the subsequent operations, to keep the root-ends even and the stalks parallel. At the same time it is desirable to have, as far as possible, stalks of equal length together—all these conditions

having considerable influence on the quality and appearance of the finished sample. As a general rule the removal of the "bolls" or capsules by the process of rippling immediately follows the pulling, the operation being performed in the field; but under some systems of cultivation, as, for example, the Courtrai method, alluded to below, the crop is made up into sheaves, dried and stacked, and is only balled and retted in the early part of the next ensuing season. The simplest type of rippler, or apparatus for separating the seed capsules from the branches, consists of a kind of comb having, set in a wooden frame, iron teeth made of round-rod iron $\frac{3}{8}$ of an inch asunder at the bottom and half an inch at the top, and 18 in. long, to allow a sufficient spring, and save much breaking of flax. The points should begin to taper 3 in. from the top. When such a rippler is used, a sheet or other cover may be spread on the field, the apparatus placed in the middle of it, and two rippers, sitting opposite each other, with the machine between them, work at the same time. Suitable machines are now made for this operation. In any case, it is inadvisable to ripple the flax so severely as to break or tear the delicate fibres at the upper part of the stem. The two valuable commercial products of the flax plant, the seeds and the stalk, are separated at this point. We have here to do with the latter only.

Retting.—*Retting* or *rotting* is an operation of the greatest importance, and one in connection with which, during the last 50 years, numerous experiments have been made, and many projects and processes put forth, with the view of remedying the defects of the primitive system or altogether supplanting it. Up to the present, however, the so-called primitive method remains the chief one. From the earliest times two leading processes of retting have been practised, termed respectively water-retting and dew-retting; and as no method has yet been introduced which satisfactorily supersedes these operations, they will first be described.

For water-retting—the process by which flax is generally prepared—pure soft water, free from iron and other materials which might colour the fibre, is essential. Any water much impregnated with lime is also specially objectionable. The dams or ponds in which the operation is conducted are of variable size, and usually between 4 and 5 ft. in depth; much retting is done in slowly running rivers. The rippled stalks are tied in small bundles and packed occasionally root downwards, but often flat, in the dams till they are quite full; over the top of the upper layer is placed a stratum of rushes and straw, or sods with the grassy side downwards, and above all stones of sufficient weight to keep the flax submerged. Under favourable circumstances a process of fermentation should immediately be set up, which soon makes itself manifest by the evolution of gaseous bubbles. After a few days the fermentation subsides; and generally in from ten days to two weeks the process ought to be complete. The exact time, however, depends upon the weather, the temperature, and the particular kind of water in which the flax is immersed. The immersion itself is a simple matter; the difficulty lies in deciding when the process is complete. If allowed to remain under water too long, the fibre is weakened by what is termed "over-retting," a condition which increases the amount of codilla in the scutching process; whilst "under-retting" leaves part of the gummy or resinous matter in the material, which hinders the subsequent preparing and spinning processes. As the steeping is such a critical operation, it is essential that the stalks be examined daily and tested as the process nears completion. When it is found that the fibre separates readily from the woody "shive" or core, the beets or small bundles are ready for removing from the dams. The plants are drained, and then spread, evenly and equally, over a grassy meadow to dry. The drying, which takes from a week to a fortnight, must be uniform, so that all the fibres may spin equally well. To secure this uniformity, it is necessary to turn the material over several times during the process. It is ready for gathering when the core cracks and separates easily from the fibre. At this point advantage is taken of fine dry weather to gather up the flax, which is now ready for breaking, but the fibre is improved by stooking and stacking it for some time before it is taken to the breaking and scutching mill.

Dew-retting is the process by which all the Archangel flax and a large portion of that sent out from Leningrad are prepared. By

this method the operation of steeping is entirely dispensed with, and the flax is, immediately after pulling, spread on the grass where it is under the influence of air, sunlight, night-dews and rain. The process is tedious, the resulting fibre is brown in colour, and it is said to be peculiarly liable to undergo heating (probably owing to the soft heavy quality of the flax) if exposed to moisture and kept closely packed with little access of air. Archangel flax is, however, peculiarly soft and silky in structure, although in all probability water-retting would result in a fibre as good or even better in quality.

Retting is really a complicated process of fermentation, as the amount of retting bacteria is regulated by the rate of movement of the water and by the temperature.

The only modification of water-retting which has hitherto endured the test of prolonged experiment, and taken a firm position as a distinct improvement, is the warm-water retting, the original of which was patented in England in 1846 by an American, Robert B. Schenck. For open pools and dams Schenck substitutes large wooden vats under cover, into which the flax is tightly packed in an upright position. The water admitted into the tanks is raised to and maintained at a temperature of from 75° to 95° F. during the whole time the flax is in steep. In a short time a brisk fermentation is set up, gases at first of pleasant odour, but subsequently becoming very repulsive, being evolved, and producing a frothy scum over the surface of the water. The whole process occupies only from 50 to 60 hours. Since that time, several other methods have been tried and only recently Dr. Pritchard's method formed the chief part of the prospectus of a new large limited company.

Breaking.—On the completion of the retting operation, the flax stalks are treated in a breaking machine, where several pairs of fluted rollers break the woody centre of the stalks into small pieces without damaging the fibrous layer. In passing, it should be stated that the fibrous layer is just under the cuticle or outer bark of the plant. Specially constructed rollers are used to feed the stalks to the fluted rollers, and other rollers to deliver the treated stalks. Scraping mechanism works in conjunction with the breaking rollers so that the bulk of the woody matter may be removed from the interior of the plant and from the fibrous layer. When this operation is finished, the fibrous layer is ready for the scutching mill. This is the process by which the woody matter not removed in the breaking is scraped off the fibrous layer, either by hand or machine.

Scutching.—Hand labour, aided by simple implements, is still much used in Continental countries both for breaking and scutching; also in some parts of Ireland where labour is cheap, or when very fine material is desired; but the use of scutching mills is now very general, these being more economical. A great many modified scutching machines and processes have been proposed and introduced with the view of promoting economy of labour and improving the turn-out of fibre, both in respect of cleanness and in producing the least proportion of codilla or scutching tow.

The celebrated Courtrai flax of Belgium is the most valuable staple in the market, on account of its fineness, strength and particularly bright colour. There the flax is dried in the field, and housed or stacked during the winter succeeding its growth, and in the spring of the following year it is retted in crates sunk in the sluggish waters of the river Lys. After the process has proceeded a certain length, the crates are withdrawn, and the sheaves taken out and stooked. It is thereafter once more tied up, placed in the crates, and sunk in the river to complete the retting process; but this double steeping is not invariably practised. When finally taken out, it is unloosed and put up in cones, instead of being grassed, and when quite dry it is stored for some time previous to undergoing the operation of scutching. In all operations the greatest care is taken, and the cultivators being peculiarly favoured as to soil, climate and water, Courtrai flax is a staple of unapproached excellence.

An experiment made by Professor Hodges of Belfast on 7,770 lb. of air-dried flax yielded the following results. By rippling he separated 1,946 lb. of bolls which yielded 910 lb. of seed. The 5,824 lb. (52 cwt.) of flax straw remaining lost in steeping 13 cwt. left 39 cwt. of retted stalks, and from that 6 cwt. 1 qr. 2 lb. (702 lb.)

of finished flax was procured. Thus the weight of the fibre was equal to about 9% of the dried flax with the bolls, 12% of the balled straw, and over 16% of the retted straw. One hundred tons treated by Schenck's method gave 33 tons bolls, with 27.50 tons of loss in steeping; 32.13 tons were separated in scutching, leaving 5.90 tons of finished fibre, with 1.47 tons of tow and pluckings. The following analysis of two varieties of heckled Belgian flax is by Dr. Hugo Müller (*Hoffmann's Berichte über die Entwicklung der chemischen Industrie*):—

	%	%
Ash	0.70	1.32
Water	8.65	10.70
Extractive matter	3.65	6.02
Fat and wax	2.39	2.37
Cellulose	82.57	71.50
Inter-cellular substance and pectose bodies	2.74	9.41

According to the determinations of Julius Wiesner (*Die Rohstoffe des Pflanzenreiches*), the fibre ranges in length from 20 to 140 centimetres, the length of the individual cells being from 2.0 to 4.0 millimetres, and the limits of breadth between 0.012 and 0.025 mm., the average being 0.016 mm.

Vicissitudes of the Trade.—Among the circumstances that have retarded improvement both in the growing and preparing of flax, the fact that, till comparatively recent times, the whole industry was conducted only on a domestic scale has had much influence. At no very remote date it was the practice in Scotland for every small farmer and cotter not only to grow "lint" or flax in small patches, but to have it retted, scutched, cleaned, spun, woven, bleached and finished entirely within the limits of his own premises, and all by members or dependents of the family. The same practice obtained and still largely prevails in other countries. Thus the flax industry was long kept away from the most powerful motives to apply to it labour-saving devices, and apart from the influence of scientific inquiry for the improvement of methods and processes. As cotton came to the front, just at the time when machine-spinning and power-loom weaving were being introduced, the result was that in many localities where flax crops had been grown for ages, the culture gradually drooped and ultimately ceased. By degrees, the operations of spinning and weaving ceased to be followed as a domestic industry, and were ultimately merged into factory processes.

For a considerable number of years before the World War, the number of areas under flax cultivation in Russia exceeded the combined areas of all the rest of Europe. There was also a complete classification of the various kinds. All this, however, has been changed and any data referring to the subject is more or less unreliable. Nevertheless, those interested in the districts in which flax culture prevails, the present methods of classification, and other particulars, can obtain these from the booklets issued by the Northern and Eastern European Trading Company, Ltd. Many attempts have been made, and are still being made, to extend the cultivation of flax in Great Britain and Ireland. Much progress has been made, but much more remains to be done, before the flax industry recovers its prestige.

See T. Woodhouse and P. Kilgour "Flax and Flax Spinning" in *The Textile Recorder* (Jan. 1917 to July 1919); F. Bradbury, *Flax Culture and Preparation* (1920). (T.W.)

FLAXMAN, JOHN (1755–1826), English sculptor and draughtsman, was born at York on July 6, 1755, the second son of John Flaxman, who carried on the trade of a moulder and seller of plaster casts at the sign of the Golden Head, New street, Covent Garden, London. Within six months after his birth the family returned to London, and in his father's back shop he spent an ailing childhood.

He early took delight in drawing and modelling from his father's stock-in-trade. In 1770 he entered as a Royal Academy student and won the silver medal. In the competition for the gold medal of the Academy in 1772, Flaxman was defeated. But this reverse proved no discouragement; he continued to work both as a student in the schools and as an exhibitor in the galleries of the Academy, occasionally also attempting diversions into the sister art of painting. To the Academy he contributed a wax model of

Neptune (1770); four portrait models in wax (1771); a terracotta bust, a wax figure of a child, a figure of History (1772); a figure of Comedy, and a relief of a Vestal (1773). During these years he received a commission from a friend of the Mathew family, for a statue of Alexander. But by heroic and ideal work of this class he could, of course, make no regular livelihood. In his 20th year he was employed by Josiah Wedgwood and his partner, Bentley, as modeller of classic and domestic friezes, plaques, ornamental vessels and medallion portraits, in "jasper" and "basalt" ware.

For 12 years, from his 20th to his 32nd (1775–1787), Flaxman subsisted chiefly by his work for the firm of Wedgwood, but by 1780 he had begun to earn something in another branch of his profession, which was in the future to furnish his chief source of livelihood, viz., the sculpture of monuments for the dead. Three of the earliest of such monuments by his hand are those of Chatterton in the church of St. Mary Redcliffe at Bristol (1780), of Mrs. Morley in Gloucester cathedral (1784), and of the Rev. T. and Mrs. Margaret Ball in the cathedral at Chichester (1785). During the rest of Flaxman's career memorial bas-reliefs of the same class occupied a principal part of his industry; they are to be found scattered in many churches throughout the length and breadth of England. The best are admirable for pathos and simplicity, and for a Greek instinct for rhythmical design and composition.

In 1782, Flaxman was married to Anne Denman. They set up house at first in Wardour street, sometimes spending their summer holidays in the house of the poet Hayley, at Earham in Sussex. In 1787 they set out for Rome. Flaxman soon ceased modelling for Wedgwood himself, but continued to direct the work for other modellers employed for the manufacture at Rome. He had intended to return after a stay of a little more than two years, but was detained by a commission for a marble group of a Fury of Athamas from the notorious Comte-Évêque, Frederick Hervey, earl of Bristol and bishop of Derry, and did not return until the summer of 1794, having in the meantime executed another commission (a "Cephalus and Aurora") for Mr. Hope, and having sent home models for several sepulchral monuments, including one in relief for the poet Collins, in Chichester cathedral, and one in the round for Lord Mansfield in Westminster Abbey.

But what gained for Flaxman in this interval a general and European fame was those outline designs to the poets, in which he showed his natural affinity to the ancients and belonged to them. The designs for the *Iliad* and *Odyssey* were commissioned by Mrs. Hare-Naylor; those for Dante by Mr. Hope; those for Aeschylus by Lady Spencer; they were all engraved by Piroli, not without considerable loss of the finer and more sensitive qualities of Flaxman's own lines.

In 1797 Flaxman was made an A.R.A. Every year he exhibited work of one class or another; occasionally a public monument in the round, like those of Paoli (1798), or Captain Montague (1802) for Westminster Abbey, of Sir William Jones for St. Mary's, Oxford (1797–1801), of Nelson or Howe for St. Paul's; more often memorials for churches, with symbolic Acts of Mercy or illustrations of Scripture texts, both commonly in low relief (Miss Morley, Chertsey [1797], Miss Cromwell, Chichester [1800], Mrs. Knight, Milton, Cambridge [1802], and many more). Soon after his election as associate, he published a scheme, half grandiose, half childish, for a monument to be erected on Greenwich hill, in the shape of a Britannia, 200 ft. high. In 1800 he was elected full academician. In 1810 he was appointed to a chair of sculpture specially created for him by the Royal Academy. The most important works which occupied Flaxman in the following years were the monument to Mrs. Baring in Micheldever church, the richest of all his monuments in relief (1805–1811); that for the Worsley family at Campsall church, Yorkshire, which is the next richest; those to Sir Joshua Reynolds for St. Paul's (1807); to Captain Webbe for India (1810); to Captains Walker and Beckett for Leeds (1811); to Lord Cornwallis for Prince of Wales's island (1812); and to Sir John Moore for Glasgow (1813).

After his Roman period he produced for a good many years

no outline designs for the engraver except three for Cowper's translations of the Latin poems of Milton (1810). Other sets of outline illustrations drawn about the same time, but not published, were one to the *Pilgrim's Progress*, and one to a Chinese tale in verse, called "The Casket." In 1817 we find him returning to his old practice of classical outline illustrations and publishing the happiest of all his series in that kind, the designs to Hesiod, excellently engraved by the sympathetic hand of Blake. Immediately afterwards he was much engaged in designing for the goldsmiths—a testimonial cup in honour of John Kemble, and following that, the great labour of the famous and beautiful though quite un-Homeric "Shield of Achilles." Almost at the same time he undertook a frieze of "Peace, Liberty and Plenty," for the duke of Bedford's sculpture gallery at Woburn, and an heroic group of Michael overthrowing Satan, for Lord Egremont's house at Petworth. His literary industry at the same time is shown by several articles on art and archaeology contributed to Rees's *Encyclopaedia* (1819–20). In 1822 he delivered at the Academy a lecture in memory of his old friend and generous fellow-craftsman, Canova, then lately dead; in 1823 he received from A. W. von Schlegel a visit of which that writer has left us the record. He died on Dec. 3, 1826.

Of his completed ideal sculptures, the "St. Michael" at Petworth is the best, and indeed is admirably composed from all points of view; but it lacks fire and force, and the finer touches of the chisel; a little bas-relief like the diploma piece of the "Apollo" and "Marpessa" in the Royal Academy compares with it favourably. This is one of the very few things which he is recorded to have executed in the marble entirely with his own hand; ordinarily he entrusted the finishing work of the chisel to Italian workmen and was content with the smooth mechanical finish which they imitated from the Roman imitations of Greek originals. Of Flaxman's complicated monuments in the round, such as the three in Westminster Abbey and the four in St. Paul's, there is scarcely one which has not something heavy and infelicitous in the arrangement. But when we come to his simple monuments in relief we find almost always a far finer quality. He did not thoroughly understand composition on the great scale and in the round, but he did thoroughly understand relief, and found scope in it for his remarkable gifts of harmonious design, and tender, grave and penetrating feeling. But if we would see even the happiest of his conceptions at their best, we must study them, not in the finished marble but rather in the casts from his studio sketches (marred though they have been by successive coats of paint intended for their protection) of which a comprehensive collection is preserved in the Flaxman gallery at University college. And the same is true of his happiest efforts in the classical and poetical vein, like the well-known relief of "Pandora Conveyed to Earth by Mercury." We can realize the most essential charm of his genius in the study, not of his modelled work at all, but of his sketches in pen and wash on paper. Of these the principal public collections are at University college, in the British Museum, and the Victoria and Albert Museum.

FLEA, a name given to insects forming the scientific order *Siphonaptera* (or *Aphaniptera*) and typically applied to the human flea (*Pulex irritans*). Fleas live as ecto-parasites on the bodies of mammals and birds, where they feed by sucking the blood. They are remarkable for their powers of leaping, and about 500 species are known. They are wingless insects with the body laterally com-

pressed, short stout antennae reposing in grooves, and the eyes minute or wanting. The mouth-parts are adapted for piercing and sucking. The skin of the host is perforated by the blade-like mandibles, and the blood is imbibed through a channel formed by these organs in close conjunction with the stylet-like labrum. Fleas pass through a complete metamorphosis: their larvae are worm-like, and live on organic refuse about the lairs of the hosts, and the pupae are enclosed in silken cocoons. The human flea is nearly cosmopolitan and, in addition to man, it also infests certain other mammals. The eggs are found on the floors, carpets, etc., of uncleanly dwellings, where the larvae feed upon particles of refuse, and the whole life-history is completed in four to six weeks. Several species of fleas infesting rats, and also known to suck the blood of man, are concerned with the spread of the bacillus of bubonic plague, the most important being *Xenopsylla cheopis*, which is the chief plague flea in India. In the "jigger" or "chigoe" (*Dermatophilus penetrans*) of the tropics the female becomes embedded in the skin of the feet of man and other hosts, where she becomes distended to the size of a small pea, and causes extreme irritation. (A. D. I.)

FLÊCHE, an architectural term which, in France, signifies any spire, but in English usage is limited to those small, slender spires which are placed on the ridge of a roof of a church and not upon a tower. The *flèche* is usually built of a wood framework covered with lead or occasionally copper and is generally of rich, light, delicate design, in which tracery, miniature buttresses and crockets have an important part. They are frequently of great height, that of Notre Dame, Paris, being nearly 100 ft. and that of Amiens, 148 feet. The *flèche* is usually placed at the intersection of nave and transepts. Reims cathedral had, however, an additional *flèche* at the summit of the apse.

FLÉCHIER, ESPRIT (1632–1710), bishop of Nîmes, was born at Pernes on June 10, 1632. He entered the Congrégation des Doctrinaires, and afterwards left it, owing to the strictness of its rules, and went to Paris. His French poems met with little success, but a description in Latin verse of a tournament given by Louis XIV. in 1662, brought him a great reputation. He subsequently became tutor to Louis Urbain Lefèvre de Caumartin (afterwards *intendant* of finances and counsellor of state), *lecteur* to the dauphin in 1668, abbot of St. Séverin, in the diocese of Poitiers, almoner to the dauphiness, bishop of Lavaur, in 1685, and in 1687 bishop of Nîmes. The edict of Nantes had been repealed two years before; but the Calvinists were still numerous at Nîmes. Fléchier, by his leniency and tact, succeeded in bringing over some of them to his views. During the troubles in the Cévennes (see HUGUENOTS) he softened to the utmost of his power the rigour of the edicts. He died at Montpellier on Feb. 16, 1710. As a preacher he cannot be compared with Bossuet or Bourdaloue, but he is always ingenious, often witty; his indisputable eloquence is sometimes marred by an affectation of symmetry and an excessive use of antithesis.

The last complete edition of Fléchier's works appeared at Paris, 1828; the *Mémoires sur les Grands Jours* was published in 1844 by B. Gonod (2nd ed., 1862). His other works are: *Histoire de Théodose le Grand* (Eng. trans. 1693); *Oraisons funèbres, Histoire du Cardinal Ximènes, Sermons de morale, Panégyriques des saints*. See A. Fabre, *Fléchier, orateur* (1886); A. Delacroix, *Vie de Fléchier* (1865).

FLECKEISEN, ALFRED (1820–1899), German philologist and critic, was born at Wolfenbüttel on Sept. 23, 1820. He was vice-principal of the Vitzthum'sches Gymnasium at Dresden from 1861 to 1889. He died on Aug. 7, 1899. Fleckeisen is chiefly known for his work on Plautus and Terence; in the knowledge of these authors he was unrivalled, except perhaps by Ritschl, his life-long friend and a worker in the same field. His chief works are: *Exercitationes Plautinae* (1842); "Analecta Plautina," printed in *Philologus*, ii. (1847); *Plauti Comoediae*, i., ii. (1850–51, unfinished), introduced by an *Epistula critica ad F. Ritschelium*; *P. Terenti Afri Comoediae* (new ed., 1898).

FLECKER, JAMES ELROY (1884–1915), was born in London on Nov. 5, 1884, the son of Rev. W. H. Flecker, and christened Herman Elroy; this name he changed to James many years later. He was educated at Dean Close School, Cheltenham,

where his father was headmaster, Uppingham and Trinity College, Oxford. Desiring to enter the consular service, he went to Caius college, Cambridge, to learn oriental languages, and he was sent to Constantinople in June 1910. The same year his *Twenty-six Poems* was published. In September, having fallen ill, he returned to England and went to a sanatorium; he returned to his post, apparently cured, in March 1911, and was transferred to Smyrna in April. In May he married, in Athens, Miss Helle Skiadaressi. He fell ill again early in 1913, and went to Switzerland; *The Golden Journey to Samarkand* was published in this year. He died at Davos on Jan. 3, 1915. The last few years of his life included, in addition to competent work at his profession and a desperate struggle with illness, a considerable poetic activity, some of it of very high quality.

He belongs to no "school," though the Parnassians are known to have had some influence on him, and his work, some of which is in every modern anthology, never seems quite at home there. Nor is it easy to describe it; of his many themes the most recurrent are Greece, the East and England, and he has best portrayed himself in *Oak and Olive*. But at least it seems safe to conjecture that some of his lyrics, between the sculptured stillness of *A Ship, an Isle* and the movement, so expressive in utterly different ways, of *Saadabad* and the *Dying Patriot* will not be forgotten. What is perhaps more disputable is Flecker's place as a dramatist. He left behind him at his death two unpublished plays, *Hassan* (Haymarket, 1923) and *Don Juan*. *Don Juan* is perhaps too slight and unequal to support a claim to dramatic genius. *Hassan* is rather a different matter. No one would call it faultless, but as a play to read, with its colour and its wit and its passion, its alternation of merriment and tragedy, and the strange beauty of its rhythms it is entirely fascinating. Flecker also wrote *The Grecians* (1910) and a novel, *The King of Alsander* (1914).

See *Collected Poems*, with an introduction by J. C. Squire (1916); *Hassan* (1922); *Don Juan* (1925); *Collected Prose* (1920 and 1922); *Letters to Frank Savory* (1926).

See also D. Goldring, *J. E. Flecker* (1922); and the *Life* by Geraldine Hodgson (1925).

FLECKNOE, RICHARD (c. 1600–c. 1678), English dramatist and poet, was probably of English birth. The few known facts of his life are derived from his *Relation of Ten Years' Travels in Europe, Asia, Affrique, and America*, consisting of letters written during his travels. He fled from the Civil War to Ghent, and in 1645 he went to Rome for Béatrix de Cusance, to secure the legalization of her marriage to Charles IV. Andrew Marvell has described him in his satire, "Flecknoe, an English Priest at Rome." He also travelled in the Levant, and in 1648 went to Brazil.

His royalist and Catholic convictions did not prevent him from writing a book in praise of Oliver Cromwell, *The Idea of His Highness Oliver . . .* (1659). This publication was discounted at the Restoration by the *Heroick Portraits* (1660) of Charles II. and others of the Stuart family. John Dryden used his name as a stalking horse from behind which to assail Thomas Shadwell in *Mac Flecknoe* (1682). The opening lines run:—

All human things are subject to decay,
And, when fate summons, monarchs must obey.
This Flecknoe found, who, like Augustus, young
Was called to empire, and had governed long;
In prose and verse was owned, without dispute,
Throughout the realms of nonsense, absolute.

Dryden's aversion seems to have been caused by Flecknoe's affectation of contempt for the players and his attacks on the immorality of the English stage. His verse, which hardly deserved his critic's sweeping condemnation, was much of it religious, and was chiefly printed for private circulation. None of his plays was acted except *Love's Dominion*, announced as a "pattern for the reformed stage" (1654). He died probably about 1678.

A *Discourse of the English Stage*, was reprinted in W. C. Hazlitt's *English Drama and Stage* (1869); Robert Southey, in his *Omniana* (1812), protested against the wholesale depreciation of Flecknoe's works. See also A. Lohr, "Richard Flecknoe," in *Münchener Beiträge zur . . . Philologie* (Leipzig, 1905).

FLEET AUXILIARY VESSELS. In addition to the fighting units—battleships, cruisers, destroyers, etc.—which go to make up a fleet, a modern navy, in war time, requires an array

of auxiliary vessels and small craft. The World War produced many varieties of such auxiliaries; some for service with the main forces, but many to perform special functions, called for by the German submarine and mine-laying campaign, or for use in connection with landing operations. In the first category were the vessels required to carry oil fuel, ammunition, provisions and stores from the naval establishments to the fleet bases; in general, merchant ships were adapted for these services. In addition, repair ships fitted with complete workshops were employed at the fleet bases. For other services, existing ships were adapted or new vessels were built. Space permits mention of the more important types only.

Armed Merchant Cruisers.—Merchant ships of large and medium size were fitted out by the British Admiralty as armed merchant cruisers. These vessels performed invaluable service in dealing with the German armed liners which were at large at the outbreak of war, a notable event in this connection being the sinking of the "Cap Trafalgar" by the "Carmania" on Sept. 14, 1914. At a later stage of the war the A.M.C.'s were principally employed on convoy duty across the Atlantic. The standard fighting equipment of the largest of these was two 6 in. B.L. guns, six 6 in. Q.F. guns, two 11 in. howitzers, two 6 pdr. or other anti-aircraft guns and four depth charges. In order to relieve some of the destroyers for essential duty with the fleet, certain vessels of cross channel type were converted into armed boarding vessels.

Convoy Sloops and Kite Balloon Ships.—Sloops classified as convoy sloops were built to resemble merchant ships. The guns were in concealed positions, and many of these vessels carried kite balloons to assist them in locating enemy submarines. As auxiliaries to these and to other fighting vessels carrying kite balloons, one or two merchant ships were taken over and fitted with powerful hydrogen plants for inflating the kite balloons. Merchant ships spotting with these balloons co-operated with the land forces during the Gallipoli campaign. They also did useful work in the Adriatic.

Whaling Ships.—In 1915, 15 vessels of whaler type were built for the conveying of merchant vessels of slow speed. The whaler type was considered to be desirable (and proved to be so on service) on account of its good manoeuvring qualities, which enabled it to cope with enemy submarines despite its slow speed. These vessels were 132 ft. long, 25 ft. beam, 8½ ft. mean draught and carried one 12 pdr. gun. They were well subdivided by bulkheads and decks to give them the maximum safety in case of underwater damage. Their gun could be effectively concealed, and a mock harpoon gun was fitted forward as an additional disguise to their real character.

Q-Ships.—No reference to the auxiliary vessels used during the war would be complete without mention of the famous Q-ships, and their campaign against the enemy submarines. Merchant vessels, both sailing and steam driven and of many different types, were fitted out with guns and depth charges which were cleverly concealed behind dummy deck houses, boats, etc. They went to sea with the deliberate object of luring submarines into attacking them, and the crews would entice the enemy to close quarters by making a show of abandoning the ship. At the critical moment the hidden guns would be revealed and fire opened on the submarine. The Q-ships were manned by naval personnel disguised as ordinary merchant seamen and their heroic deeds were responsible for the destruction of a considerable number of submarines, although the ships themselves did not emerge from their campaign without numerous losses.

Mine-Sweepers and Trawlers.—The extensive minelaying operations of the Germans called for the provision of many mine-sweeping vessels. A number of smaller merchant ships were taken over for this purpose at the outset of the war, but it soon became necessary to build vessels specially suited to mine-sweeping as the demand became greater. Altogether about 100 of these vessels were built, merchant practice being adopted in order to simplify their construction and to bring them within the capacity of the smaller shipyards. They were of 750 tons displacement, and the 1,800 h.p. machinery provided enabled them to reach a full speed of 17 knots. They proved capable of remaining afloat after the

most severe damage from mines. Ordinary steam fishing trawlers were also used for mine-sweeping.

P.Boats.—Patrol boats of the "P" class were designed to relieve destroyers of such duties as patrolling, escort work and operations against submarines. High speed was not a necessity for the particular work which they had to undertake, but their 22 knots was sufficient to overtake submarines, and their top-hammer was kept as low as possible to avoid their being easily visible. They were of 600 tons displacement and developed full speed with 3,800 h.p. geared turbines, and carried one 4 in. and one 2 pdr. gun and two 14 in. torpedo tubes. They proved very economical and efficient boats, especially in anti-submarine work.

Coastal Motor Boats.—A great deal of useful work in attacking submarines, in patrolling the coast and in operations against enemy bases on the Belgian coast was performed by the large fleet of coastal motor boats which were built during the war. These boats varied from 40 ft. in length in the earlier types to 70 ft. in the later design and the speeds varied from 30 to 37 knots. They were fitted with Lewis guns and depth charge apparatus and could carry alternatively either a mine or one or two 18 in. torpedoes. They took part in many operations attended with great risks, notably in the raids on Zeebrugge and Ostend.

Oilers, Ammunition Ships, etc.—The Admiralty also designed some fast fleet oilers which could carry 5,000 tons of oil at a speed of 15 knots. Many other types of auxiliary ships were designed and constructed including ammunition ships, gunboats for patrol work and also of special type for work in Mesopotamia, self-propelled lighters for landing troops, guns, etc., and blockships. In the last-named class are the "Vindictive" and her sister blockships which were used in the raids on Zeebrugge and Ostend. (See BELGIAN COAST OPERATIONS.)

Sloops, minelayers, minesweepers and fleet supply ships are necessary auxiliaries to modern navies, and are to be found in varying strength but similar in type to those described in the fleets of the principal sea powers. (See also MINELAYING; MINE-SWEEPING.)

(W. J. B.)

See Jane's *Fighting Ships*; Brassey's *Naval and Shipping Annual*.

FLEET, NAVAL. "Fleet" usually implies a collection of ships in company, particularly one consisting of a large number of warships: or it is "The collective naval force of a country" (Webster). It is also used in connection with a collection of fishing vessels and in sea fishing it is used to mean a row of drift nets secured together. The term is derived from the root of the verb "to fleet," O.Eng. *fleetan*—to float, to flow. In the British Navy the bigger sea commands are usually referred to as fleets, e.g., Mediterranean Fleet, and the smaller commands as squadrons, e.g., First Cruiser Squadron. (See also ADMIRAL.)

A fleet, in its naval sense, is generally composed of a number of squadrons of different types of ships, such as the battle squadron, battle cruiser squadron, cruiser squadron, as well as groups of lighter vessels which are more often referred to as flotillas, e.g., a destroyer or submarine flotilla. The larger formations may be sub-divided for manoeuvring and administrative purposes into divisions; for instance the battleships of the British Grand Fleet in one of its organisations were grouped in seven divisions. Normally each division of battleships or a squadron of cruisers is commanded by a flag officer. Destroyer flotillas are commanded by captains and half flotillas by commanders. (See also DESTROYER.) The commander-in-chief generally flies his flag in a fleet flag-ship, usually a battleship, which is independent of the various organisations but which takes her allotted place in the battle line.

A Fleet at Sea.—In order to understand the elementary principles of handling a fleet at sea, it is necessary to define certain simple formations.

Line ahead (American term, Column). (Fig. 1) Ships in single line, one astern of the other.

Line abreast (American term, Line). Ships in single line, each abreast of the other.

Quarter line (the American term is line of bearing followed by the inclination to the squadron course in degrees, thus, "line of bearing, 50°). Ships in single line, disposed on a bearing of 45°

from a line astern of the leading ship. Ships may also be disposed on any other line of bearing from the flagship or appointed leader.

With a great number of ships in company it is inconvenient to keep station in a very long single line, therefore divisional formations are resorted to.

Divisions in line ahead—disposed abeam (American term, Line of division columns). (Fig. 2.) In this formation the ships of each division are in line ahead while the divisions are disposed abreast of each other; the distance between the lines, for manoeuvring purposes, is one equal to the length of each division. From the diagram it will be seen that this enables the whole fleet to be formed into single line by the simple method of each division wheeling astern of its leader. This process is known as deploying and is one of the methods of getting into battle formation from cruising formation. (See also JUTLAND, BATTLE OF.)

FIG. 1.—DIAGRAM OF FLEET FORMATIONS WITH UNITS KEEPING STATION $2\frac{1}{2}$ CABLE LENGTHS (500 YARDS) FROM ONE ANOTHER, RECKONING FROM BOW TO BOW

A Fleet in Battle.—A considerable amount of freedom of movement in battle is allowed to the commanders of individual squadrons, especially in the case of cruisers and destroyers. A certain amount of independence is also permissible to the flag officers commanding the divisions of a battle fleet, but in the handling of a fleet certain essentials must always govern any efforts at individual initiative. Principal among these are: (a) Collisions must be avoided, (b) Ships of lesser importance should not interfere with the gun-fire or other means of offense of ships of greater importance as regards their ability to inflict damage on the enemy. (c) The fleet must not become so divided that the enemy can defeat it piecemeal. This particularly applies in the case of the battle fleet. Where a force has greatly superior speed to the heavier ships of the enemy fleet, such as a squadron of battle cruisers or a fast battle squadron, like the 5th Battle Squadron at Jutland (*q.v.*), a considerable measure of individual tactics may be employed with advantage, but at all times it is of great importance that every group and unit composing a fleet should understand and conform to the principles governing the general tactical plan of the commander-in-chief.

The development of aircraft and the advent of the aircraft carrier as a fleet unit are likely to have a very considerable effect

FIG. 2.—DIAGRAM OF A FLEET IN DIVISIONS IN LINE AHEAD, DISPOSED ABEAM, SHOWING METHOD OF DEPLOYMENT INTO SINGLE LINE AHEAD

on the future conduct of fleets in action. Where air observation is available on both sides, the element of surprise between rival fleets to a large extent disappears, as the respective commanders will be informed of their adversary's movements while they are still a long way out of sight of each other. This same influence will make itself felt in the manner of engaging. On the one hand it may bring about an action, on the other it may enable a weaker force to escape. The effect may well be to enhance the strategical importance of darkness.

FLEET PRISON, an historic London prison, formerly situated on the east side of Farringdon street, and deriving its name from the Fleet stream. It became prominent from being used as a

place of reception for persons committed by the Star Chamber, and, afterwards, for debtors, and persons imprisoned for contempt of court by the court of chancery. It was burnt down in the great fire of 1666; rebuilt, destroyed in the Gordon riots of 1780 and again rebuilt in 1781-82. In pursuance of an act of 1842 by which the Marshalsea, Fleet and Queen's Bench prisons were consolidated under the name of Queen's prison, it was finally closed, and in 1844 sold to the corporation of the City and pulled down. The head of the prison was termed "the warden," who was appointed by patent. It became a frequent practice of the holder of the patent to "farm out" the prison to the highest bidder. It was this custom which made the Fleet prison long notorious for the cruelties inflicted on prisoners. The liberties or rules of the Fleet were the limits within which particular prisoners were allowed to reside outside the prison walls subject to certain conditions.

Fleet Marriages.—By the common law a marriage was valid if the ceremony was conducted by a person in holy orders, even if those orders were not of the Church of England. Neither banns nor licence were necessary, and the time and place were alike immaterial. Thus, in the period of laxness which succeeded the Commonwealth, resulted innumerable clandestine marriages. They were contracted at first to avoid expense, but an act of 1696, which imposed a penalty of £100 on any clergyman who celebrated, or permitted another to celebrate, a marriage otherwise than by banns or licence, acted as a considerable check. To clergymen imprisoned for debt in the Fleet, however, such a penalty had no terrors, for they had "neither liberty, money nor credit to lose by any proceedings the bishop might institute against them." The earliest recorded date of a Fleet marriage is 1613, while the earliest recorded in a Fleet register took place in 1674, but it was only on the prohibition of marriage without banns or licence that they began to be clandestine. Then arose keen competition, and "many of the Fleet parsons and tavern-keepers in the neighbourhood fitted up a room in their respective lodgings or houses as a chapel," and employed touts to solicit custom for them. The scandal and abuses brought about by these clandestine marriages became so great that they became the object of special legislation. Lord Hardwicke's Act, 1753, required, under pain of nullity, that banns should be published according to the rubric, or a licence obtained, and that, in either case, the marriage should be solemnized in church; and that in the case of minors, marriage by licence must be by the consent of parent or guardian. This act put a stop to clandestine marriages in England, and henceforth couples had to fare to Gretna Green (q.v.).

The Fleet Registers eventually came into private hands, but were purchased by the Government in 1821, and are now deposited in the office of the registrar-general, Somerset House. Their dates range from 1686 to 1754. In 1840 they were declared not admissible as evidence to prove a marriage.

See J. S. Burn, *The Fleet Registers; comprising the History of Fleet Marriages, and some Account of the Parsons and Marriage-house Keepers*, etc. (1833); J. Ashton, *The Fleet: its River, Prison and Marriages* (1888).

FLEETWOOD, CHARLES (d. 1692), English soldier and politician, third son of Sir Miles Fleetwood of Aldwinkle, Northamptonshire, and of Anne, daughter of Nicholas Luke of Woodend, Bedfordshire, was admitted into Gray's Inn on Nov. 30, 1638. At the beginning of the Great Rebellion, he joined Essex's life-guard, was wounded at the first battle of Newbury, obtained a regiment in 1644 and fought at Naseby. He had already been appointed receiver of the court of wards, and in 1646 became member of parliament for Marlborough. He was said to have been the principal author of the plot to seize King Charles at Holmby, but he did not participate in the king's trial. In 1649 he was appointed a governor of the isle of Wight, and in 1650, as lieutenant-general of the horse, took part in Cromwell's campaign in Scotland and assisted in the victory of Dunbar. Next year he was elected a member of the council of state, was entrusted with the command of the forces in England, and shared in the final triumph at Worcester. In 1652 he married Cromwell's daughter, Bridget, widow of Ireton, and was made commander-in-chief in

Ireland, to which title that of lord deputy was added. During his administration (1652-55) he carried out ruthlessly the settlement of the soldiers on the confiscated estates and the transplantation of the original owners. He showed great severity in the prosecution of the Roman Catholic priests, and favoured the Anabaptists and the extreme Puritan sects to the disadvantage of the moderate Presbyterians.

Fleetwood was a strong and unswerving follower of Cromwell's policy. In Dec. 1654 he became a member of the council, and after his return to England in 1655 was appointed one of the major-generals. On Cromwell's death, he was regarded as a likely successor, and it is said that Cromwell had in fact so nominated him. He, however, supported Richard Cromwell, but allowed subsequently, if he did not instigate, petitions from the army demanding its independence, and finally compelled Richard by force to dissolve parliament. His project of re-establishing Richard in close dependence upon the army met with failure, and the Long Parliament was recalled. Fleetwood became a member of the committee of safety and of the council of state, and one of the seven commissioners for the army; on June 9 he was nominated commander-in-chief. But on Oct. 11 parliament declared his commission void. The next day he assisted Lambert in his expulsion of the parliament and was reappointed commander-in-chief. On Monk's approach from the North, he stayed in London and maintained order. The army on Dec. 24 restored the Rump, when he was deprived of his command and ordered to appear before parliament to answer for his conduct. At the Restoration he was included among the eighteen who were punished only by perpetual exclusion from public office, and his public career therefore closed, though he survived till Oct. 4, 1692.

FLEETWOOD, WILLIAM (1656-1723), English divine, was born in the Tower of London on New Year's Day 1656. He was educated at Eton and King's College, Cambridge. About the time of the Revolution he took orders, and became bishop of St. Asaph (1708), then of Ely (1714). He died at Tottenham on Aug. 4, 1723. Fleetwood's opposition to the doctrine of non-resistance brought him into conflict with the Tory ministry of 1712 and with Swift, but he never entered into personal controversy.

His principal writings are—*An Essay on Miracles* (1701); *Chronicon preciosum* (an account of the English coinage, 1707); and *Free Sermons* (1712), containing discourses on the death of Queen Mary, the duke of Gloucester and King William. The preface to this last was condemned to public burning by parliament, but, as No. 384 of *The Spectator*, circulated more widely than ever. A collected edition of his works, with a biographical preface, was published in 1737.

FLEETWOOD, a seaport and watering-place in the Fylde parliamentary division of Lancashire, England, at the mouth of the Wyre, 22½ m. N.W. by N. from London, at the terminus of a branch from Preston of the L.M.S. railway. Pop. of urban district (1931) 22,983. It dates its rise from 1836, and takes its name from Sir Peter Hesketh Fleetwood, by whom it was laid out. The seaward views, especially northward over Morecambe Bay, are fine. There are a town hall and public library. The dock is provided with railways and traffic equipment, including a grain elevator. The shipping is chiefly in the coasting and Irish trade. Passenger steamers serve Belfast and the Isle of Man, and other ports during the season. The fisheries are important, and there are salt-works in the neighbourhood. There is a promenade, with other appointments of a watering-place. The council owns the electricity undertaking; the Blackpool tramways serve Fleetwood. Rossall school, to the south-west, is one of the leading public schools in the north of England. Rossall Hall was the seat of Sir Peter Fleetwood, but was converted to the uses of the school on its foundation in 1844.

FLEGEL, EDWARD ROBERT (1855-1886), German traveller in West Africa, was born on Oct. 1, 1855, at Vilna. He obtained in 1875 a position in Lagos, West Africa. In 1879 he ascended the Benue river some 125 m. above the farthest point hitherto reached; he then received a commission from the German African Society to explore the whole Benue district. In 1880 he went up the Niger to Gomba, and then visited Sokoto, where he obtained a safe-conduct from the sultan for his intended expedi-

tion to Adamawa. This expedition was undertaken in 1882, and on Aug. 18 Flegel discovered the source of the Benue near Ngaundere. In 1883-84 he made another journey up the Benue. After a short absence in Europe Flegel returned to Africa in April 1885 with a commission to open up the Niger-Benue district to German influence; that is, to prevent Nigeria becoming British. The mission failed, and Flegel died at Brass, at the mouth of the Niger, on Sept. 11, 1886.

Flegel wrote *Lose Blätter aus dem Tagebuche meiner Haussaafreunde* (Hamburg, 1885), and *Vom Niger-Benuë; Briefe aus Afrika* (edit. by K. Flegel, Leipzig, 1890). See also "Il Giornale dell' ultimo viaggio . . . di E. Flegel," in *L'esplorazione Com.* v. viii. (1893).

FLEISCHER, HEINRICH LEBERECHT (1801-1888), German orientalist, was born at Schandau, Saxony, on Feb. 21, 1801. He was professor of oriental languages at Leipzig university from 1836 until his death (Feb. 10, 1888). His most important works were editions of Abulfeda's *Historia ante-Islamica* (1831-34), and Beidhawi's *Commentary on the Koran* (1846-48).

FLÉMAL or **FLEMAEL, BERTHOLET** (1614-1675), a Flemish painter, born at Liège on May 23, 1614. He studied under Henri Trippez and Gerard Douffet. He went to Italy in 1638, returning via Paris, where he decorated the churches of the Grands Augustines and the Carmes Déchaussés. He returned to Liège in 1663. In 1670 he was elected member of the Paris Academy, and he painted the ceiling of the audience chamber in the Tuileries (destroyed in 1871). He is one of the most important masters of the later Flemish school, a pioneer of the classicist movement in his country. His style is modelled on that of Poussin. Most of his numerous religious pictures in the churches of Liège were destroyed and lost during the French Revolution. However, there are several works still extant in the cathedral and in the churches of St. Jean, St. Barthelemy and St. Croix. Others are in the museums of Liège, Bamberg, Brussels, Dresden, Fontainebleau, Cassel, Stockholm, Niort, and in the Louvre. Flémal was also a distinguished portrait painter. His self portrait was engraved by Jean Duvivier.

FLÉMALLE, LE MAÎTRE DE: see CAMPIN, ROBERT.

FLEMING, JOHN AMBROSE (1849-), English physicist, was born at Lancaster on Nov. 29, 1849. He studied at London and Cambridge, and held the posts of lecturer in applied mechanics, Cambridge, and professor of electrical engineering, University college, London (1885-1926). Fleming is a pioneer in the applications of electrical science. He has carried out original investigations and has taken a prominent part in applying his and other people's researches to the development of electric lighting and wireless telegraphy and telephony. Fleming's earliest researches were on electrolysis but he soon turned his attention to the problem of the electric glow lamp of which he was one of the earliest investigators. In a large number of ways Fleming helped in the development of the practical application of the glow lamp, he installed electric lighting on one of the first ships of the Royal Navy to be so equipped. He acted in an advisory capacity from 1882 to 1894 to the Edison Electric Light company and later he was with the Edison and Swan company. Fleming also assisted various corporations in matters concerned with electric lighting.

While making investigations on the glow lamp Fleming observed phenomena which led him to a study of thermionics and in 1904 he made the first form of thermionic valve. He has helped to develop it and to make it the important instrument it now is in wireless. In addition to numerous other services to wireless, Fleming gave scientific assistance and helped with some of the constructional work on the first long-distance wireless station at Poldau. He also helped in the development of telephony and in 1879 acted as scientific adviser to the Edison Telephone company which was formed to set up telephone exchanges in London. Fleming invented a cymometer to measure wave lengths and an oscillating valve detector of electric waves. In conjunction with Dewar he carried out a series of investigations on the magnetic and electric properties of metals at low temperatures.

Fleming is a member of numerous learned societies and has been

awarded a number of honorary degrees. He has received the Hughes medal of the Royal Society (1910), the Albert Medal of the Royal Society of Arts (1921), and a number of other medals.

Amongst the numerous books written by Fleming are *Handbook of the Electrical Laboratory and Testing Room* (1901); *Waves and Ripples in Water, Air and Aether* (1902); *Alternate Current Transformer*; *Principles of Electric Wave Telegraphy* (1906); *Manual of Radiotelegraphy and Telephony* (1908); *The Thermionic Valve in Radiotelegraphy* (1919); *Fifty Years of Electricity* (1921); *Electrons, Electric Waves and Wireless Telephony* (1923); *The Interaction of Scientific Research and Electrical Engineering* (1927).

FLEMING, PAUL (1609-1640), German poet, was born at Hartenstein in the Saxon Erzgebirge, on Oct. 5, 1609, the son of the village pastor. He studied at Leipzig until driven away by the troubles of the Thirty Years' War. He was attached by Duke Frederick of Holstein-Gottorp to an embassy (1634-39) to Russia and Persia, to which the famous traveller Adam Olearius was secretary. Fleming died at Hamburg on April 2, 1640.

Though belonging to the school of Martin Opitz, Fleming is distinguished from most of his contemporaries by the ring of genuine feeling and religious fervour that pervades his lyric poems, even his occasional pieces.

Fleming's *Teutsche Poëmata* (pr. 1642) were edited by J. M. Lapenberg, in the Bibliothek des litterarischen Vereins (2 vols., 1863; a third volume, 1866, contains Fleming's Latin poems). Selections by J. Tittmann in *Deutsche Dichter des siebzehnten Jahrhunderts* (Leipzig, vol. ii., 1870), and by H. Österley (Stuttgart, 1885). See Rost, *Paul Fleming* (1909).

FLEMING, RICHARD (c. 1360-1431), bishop of Lincoln, and founder of Lincoln college, Oxford, was born in Yorkshire of a good family, and educated at University college, Oxford. He was made prebendary of York in 1406. Becoming an ardent Wycliffite, he incurred the censure of Archbishop Arundel. He afterwards became one of Wycliffe's most determined opponents, and to him was entrusted the execution of the decree of the council for the exhumation and burning of Wycliffe's remains. Before 1415 he was rector of Boston, Lincolnshire, and in 1420 became bishop of Lincoln. In 1423 he attended the councils of Pavia and Siena, and on his return, the see of York being vacant, the pope conferred it on Fleming; but Henry V. refused to confirm the appointment. In 1427 Fleming obtained the royal licence empowering him to found a college at Oxford for the training of disputants against Wycliffe's heresy. He died at Sleaford on Jan. 26, 1431.

FLEMING, SIR SANDFORD (1827-1915), Canadian engineer and publicist, was born at Kirkcaldy, Scotland, on Jan. 7, 1827, but in 1845 emigrated to Canada, where he was from 1867 to 1880 chief engineer of the Dominion Government. Under his control were constructed the Intercolonial Railway and much of the Canadian Pacific. After his retirement in 1880, when the Canadian Government handed over the construction of the latter to the Canadian Pacific Railway Company, he devoted himself to the study of Canadian and imperial problems, such as the unification of time reckoning throughout the world, and the construction of a state-owned system of telegraphs throughout the British empire. He saw the first link forged in the chain, in the opening in 1902 of the Pacific Cable between Canada and Australia. He advocated Federation in 1864-67, and in 1891 attacked the Liberal policy of unrestricted reciprocity with the United States. He died on July 22, 1915, at Halifax, Nova Scotia. He received the C.M.G. in 1877 and the K.C.M.G. in 1897.

He published *The Intercolonial: a historical sketch 1832-76* (Montreal and London, 1876); *England and Canada* (London, 1884); and numerous brochures and magazine articles.

See L. J. Burpee, *Sandford Fleming, Empire-Builder* (with bibliography, 1915).

FLEMING, SIR THOMAS (1544-1613), English judge, was born at Newport, Isle of Wight, and was called to the bar at Lincoln's Inn in 1574. He sat in parliament from 1584 to 1601. He was recorder of London (1594), solicitor-general (1595), chief baron of the exchequer (1604), and chief justice of the king's bench (1607). He was one of the judges at the trial of the

post-nati in 1608, siding with the majority of the judges in declaring that persons born in Scotland after the accession of James I. were entitled to the privileges of natural-born subjects in England. He died on Aug. 7, 1613, at his seat, Stoneham Park, Hampshire.

FLEMISH LANGUAGE, THE. Flemish is spoken in the northern half of Belgium and by more than 200,000 persons in the Nord Departement of France, where the boundary formerly ran much farther south. In Belgium its position has not changed much since the middle ages.

The Flemish language owes its existence and its character to the Salian Franks, who settled in the fertile valleys of the Scheldt and Lys, while it is believed that Ripuarians occupied Limburg. Teutonic occupation can be traced to the time of Caesar when the Belgians differed in speech from the other Gauls, most of them being descended from Teutons, who crossed the Rhine long before (*de Bello Gallico*, ii., 4), while Teutonic tribes were living on the left side of the Rhine (*ibid.*, 3).

Flemish means literally and originally the language or dialect of Flanders. Maerlant quotes it in this sense in his *Leven van St. Franciscus*, v. 133, together with Duuts, Brabants and Zeeus. It began to be used in writing in the first half of the 13th century. The poem of Reinaert was composed about that time. But very soon literary production became abundant. Maerlant's example shows that the need for a language more generally accessible than a local dialect was already felt. That language was known as "Dietsch." There were, of course, differences between the Dietsch of Flanders, Brabant and Limburg. For instance, *uu*, the mutation of *ie* (*cf.* "Duutsch" as against "Dietsch") was not used in the first-named province, and people pronounced there *du best*, *hi es*, *mes*—instead of *du bist*, *hi is*, *mis*. In the last-named province, *ich*, *mich* were used and mutation was a regular phenomenon. As to the vocabulary, the three provinces were bilingual. Literary influences came chiefly from the south, French words crept in, generally in the form of the neighbouring Picardian dialect, as is shown by the initial sound for example in *kasteel*, *kans*, *kaatsen*. New words were formed by adding French suffixes to Flemish stems and the purity of the language suffered from gallicisms. The chambers of rhetoric aggravated the evil and under the rule of the house of Burgundy, French became compulsory at court and council. At the same time economic changes were in progress. The decadence of Bruges prepared the rise of Antwerp, the hegemony of Flanders shifted in the 16th century to Brabant: *Dietsch* became *Duutsch* or *Duytsch*. By the end of that century the Dietsch speaking countries were cleft in two, the seven northern provinces fighting successfully for their independence and religious freedom, the south remaining Spanish and Catholic.

As "the unity of a language can be kept up only by free and uniform intercourse between all the members of the community which speak the language," the political and religious estrangement between the north and the south was a serious threat to the unity of Dietsch. The differentiation would have been enhanced but for the flight from the Spanish tyranny of many thousands who left their homes in Flanders and Brabant and carried to Holland and Zealand their energy, enterprise, science, wealth and habits of speech, the influence of which is only now beginning to be investigated thoroughly. (*See DUTCH.*) Gradually the language of the Dutch Republic began to be considered in Belgium as that of the enemy and the heretic, and an opposition was created between Dutch and Flemish, so that after the revolution of 1830, when the attempt was made to realize unity of spelling between the two, it was opposed in parliament.

For nearly three centuries Flemish led a stagnant life. It had no cultural centre, like Amsterdam or Paris. It was the language of a nation cut off from its natural relations, while its higher classes and its fellow-citizens spoke French, so that many gallicisms, *i.e.*, literally-translated French expressions, appear in the works of many writers in the past, and are now becoming rarer. The somewhat archaic character of Flemish is thus explained.

While the Dutch language (*q.v.*) is getting rid of inflexions and simplifying the grammatical gender of the nouns and the government of prepositions, Flemish retains declensions, the loss of endings being considered in conservative quarters as an impoverish-

ment. It distinguishes a merely grammatical masculine and feminine gender; *gij* (*ge*) is the only personal pronoun of the second person, the Dutch *U* being unknown. There are other differences. For instance, in Flemish *schoon*, *kus*, *smijten* are used, not *mooi*, *zoen*, *gooien*; *ijzeren weg* not *spoorweg*; *rekenschap* instead of *rekening*; it mixes up *gelukken* and *slagen*; it forms, with the prefix *her*, many more verbs denoting repetition than Dutch.

Spoken Flemish is mainly dialect—each having its characteristic features. Thus initial *h* is dropped (except in Limburg), the difference between subject and object case has disappeared. Flemish has preserved the old *f* and *û* (*scriven*, *huus*) and *ou* from *al* or *ol*, before dentals, sounds as English *oo* in *book*. Brabant with part of east Flanders has diphthongized the three sounds into *ai*, *oi*, *au*. The Germanic *ai*, *au*, which have become monophthongs (*ee*, *oo*) in written Flemish, sound as diphthongs (*ie*, *ue*); Limburg has preserved the Germanic *û*, though in the south it has become *au*, (*hûs*, *haus*) and in *al*, *ol* followed by a dental, the liquid has been dropped and the vowel lengthened. The dialect of Flanders also preserves the old *e*-ending of many feminine nouns, suffixes, *i*-stem adjectives and adverbs. In the novels of Teirlinck one encounters the words *vrouwe*, *ruste*, *mane*, *klinke*, *splete*, *ziele*, *katte*, *geruchte*, *gezichte*, *stille*, *dichte*, *omhoog* instead of *vrouw*, *rust*, and so on. Negative sentences have *en . . . niet*, as in French *ne . . . pas*.

Some of the best authors write for literary purposes an artificial but picturesque language which is neither dialect nor common Flemish. On the other hand, thanks to the literary congresses, the first of which was held in 1849, and to the teaching of the universities, the number of those whose speech differs slightly or not at all from Dutch is increasing year by year.

FLensburg (Danish, *Flensborg*), a seaport in the Prussian province of Schleswig-Holstein, at the head of the Flensburg Fjord, 20 m. N.W. from Schleswig, at the junction of the main line Altona-Vamdrup (Denmark). Pop. (1925) 63,447.

Flensburg was probably founded in the 12th century. It attained municipal privileges in 1284, was frequently pillaged by the Swedes after 1643, and in 1848 became the capital, under Danish rule, of Schleswig. In the plebiscite after the war of 1914-18 it voted itself in Germany. The principal public buildings are the Nikolaikirche (built 1390, restored 1894), with a spire 295 ft. high and the Marienkirche, also a mediaeval church, with a lofty tower. There are schools of marine engineering, navigation, wood-carving and agriculture. Flensburg is the most important town in what was formerly the duchy of Schleswig. It possesses excellent wharves, does a large trade in coal, is famous for fish curing, and has shipbuilding yards, sugar, and paper factories, glass-works, copper-works, soap-works and iron foundries. Its former extensive trade with the West Indies has lately suffered owing to the enormous development of the North Sea ports, but it is still largely engaged in the Greenland whale and the oyster fisheries.

FLERS, ROBERT DE LA MOTTE-ANGO, MARQUIS DE (1872-1927), French dramatist, born at Pont l'Évêque on Nov. 25, 1872, died at Vittel on July 30, 1927. His literary career opened with a volume of travel sketches (*Vers l'Orient*, 1896) and a series of critical essays notable for their delicacy of touch. He was on the staff of the *Soleil* and subsequently of *Figaro*. About 1900 he made the acquaintance of Arman de Caillavet, who was his close friend and collaborator for fifteen years. Their first theatrical venture was *Les Travaux d'Hercule* (1901), a mythological parody somewhat in the style of *La Belle Hélène* and *Orphée aux Enfers* by Meilhac and Halévy. They found in Cl. Terrasse a composer gifted with a comic verve comparable to that of Offenbach. Terrasse contributed greatly to the success of *Le Sire de Vergy* (1903) and *Monsieur de la Palisse* (1904). De Flers and Caillavet however achieved their greatest successes after 1906; special mention is due to *Miquette et sa Mère* (1906), *L'Amour veille* (1907), *Papa* (1911), *Primerose* (1911) and *La Belle Aventure* (1913), written in collaboration with Étienne Rey. Those of their plays which seem most likely to live are *Le Roi*

(1908), which was written in collaboration with Emm-Arène, *Le Bois Sacré* (1910) and *L'Habit Vert* (1913), in which the political and literary life of the day are exposed to lively and good-humoured satire. Robert de Flers was mobilized on the outbreak of the World War, and was at one time entrusted with an important mission to the Rumanian army. He was elected to the *Académie française* on June 3, 1920, in place of the marquis de Ségur. After the death of Arman de Caillavet in 1915 Robert de Flers collaborated with Fr. de Croisset. The best of their joint works are *Le Retour* (1920), *Les Vignes du Seigneur* (1923) and *Les Nouveaux Messieurs* (1925). Robert de Flers was for some years president of the Society of Dramatic Authors. He married a daughter of Victorien Sardou. The plays of Robert de Flers have often been compared with those of Meilhac and Halévy; but, charming and lively as they are, it is not certain that they show the sound observation and the ingenious fancy which give the work of the latter writers its lasting value.

FLERS, a manufacturing town of north-western France, in the arrondissement of Domfront, and department of the Orne, on the Vère, 41 m. S. of Caen on the railway to Laval. Pop. (1926) 10,756. There is a restored château of the 15th century. Flers has a tribunal of commerce and a board of trade-arbitrators. It is the centre of a cotton and linen-manufacturing region which includes the towns of Condé-sur-Noireau and La Ferté-Macé. Bricks and tiles, drugs, chemicals and dyes are made.

FLETA, a treatise on the common law of England written about the year 1290. It is little better than an ill-arranged epitome of Bracton. The author also borrowed some information on husbandry from Walter of Henley. He is supposed to have written it during his confinement in the Fleet prison, hence the name. *Fleta* was first printed by Selden in 1647.

FLETCHER, ALICE CUNNINGHAM (1845-1923), American ethnologist, was born in Boston (Mass.) in 1845. She studied the remains of Indian civilization in the Ohio and Mississippi valleys, became a member of the Archaeological institute of America in 1879, and worked and lived with the Omahas as a representative of the Peabody museum of American Archaeology and Ethnology, Harvard university. In 1883 she was appointed special agent to allot lands to the Omaha tribes; in 1884 prepared and sent to the New Orleans Exposition an exhibit showing the progress of civilization among the Indians of North America in the quarter-century previous, in 1886 visited the natives of Alaska and the Aleutian islands on a mission from the commissioner of education, and in 1887 was United States special agent in the distribution of lands among the Winnebagoes and Nez Percés. She was made assistant in ethnology at the Peabody museum in 1882, and received the Thaw fellowship in 1891; was president of the Anthropological Society of Washington and of the American Folk-lore Society, and vice-president of the American Association for the Advancement of Science; and working in co-operation with the Woman's National Indian Association, introduced a system of making small loans to Indians, wherewith they might buy land and houses. In 1888 she published *Indian Education and Civilization*, a special report of the Bureau of Education. She published also *Indian Story and Song from North America* (1900), illustrating "a stage of development antecedent to that in which culture music appeared." She died in Washington (D.C.), April 6, 1923.

FLETCHER, ANDREW, of Saltoun (1655-1716), Scottish politician, was the son and heir of Sir Robert Fletcher (1625-1664), and was born at Saltoun (Saltoun), East Lothian. He was a member of the Scottish parliament which met in 1681. Fletcher was a fearless and active opponent of Lauderdale's administration. He left Scotland about 1682, subsequently spending some time in Holland as an associate of the duke of Monmouth and other malcontents. He accompanied Monmouth to the west of England, but left the army after killing one of the duke's trusted advisers.

During the next few years he is said to have travelled in Spain, and he fought against the Turks in Hungary. Having in his absence from Scotland lost his estates and been sentenced to death, he joined William of Orange at The Hague. On William's accession his estates were restored to him; he soon became a

leading member of the "club," an organization which aimed at reducing the power of the crown in Scotland, and an active opponent of the English government. In 1703, at a critical stage in the history of Scotland, Fletcher again became a member of the Scottish parliament. The failure of the Darien expedition had aroused a strong feeling of resentment against England, and Fletcher and the national party seized the opportunity to obtain a greater degree of independence for their country. In the negotiations for the union of the two kingdoms Fletcher performed essential service. He got the act of security passed, which declared that the two crowns should not pass to the same head till Scotland was secured in her liberties civil and religious. Therefore Lord Godolphin was forced into the Union, to avoid a civil war after the queen's demise.

After the passing of the Act of Union, Fletcher retired from public life. He did a real, if homely, service to his country by introducing from Holland machinery for sifting grain. He died in London in Sept. 1716.

Fletcher was a fine scholar and a graceful writer. His chief works are: *A Discourse of Government relating to Militias* (1698); *Two Discourses concerning the Affairs of Scotland* (1698); and *An Account of a Conversation concerning a right regulation of Governments for the common good of Mankind* (1704), which contained his well-known remark, "I knew a very wise man so much of Sir Christopher's (Sir C. Musgrave) sentiment, that he believed if a man were permitted to make all the ballads, he need not care who should make the laws of a nation."

See *The Political Works of Andrew Fletcher* (1737); D. S. Erskine, 11th earl of Buchan, *Essay on the Lives of Fletcher of Saltoun and the Poet Thomson* (1792).

FLETCHER, GILES (c. 1548-1611), English author, son of Richard Fletcher, vicar of Cranbrook, Kent, and father of the poets Phineas and Giles Fletcher, was born in 1548 or 1549, and educated at Eton and King's college, Cambridge. In 1580 he married Joan Sheafe, of Cranbrook. In 1585 he sat in parliament for Winchelsea. He was employed on diplomatic service in Scotland, Germany and Holland, and in 1588 was sent to Russia to the court of Tsar Theodore, with instructions to conclude an alliance between England and Russia, to restore English trade, and to obtain better conditions for the English Russia company. The factor of the company, Jerome Horsey, had already obtained large concessions through the favour of the protector, Boris Godunov, but when Dr. Fletcher reached Moscow in 1588 he found that Godunov's interest was alienated, and that the Russian Government was contemplating an alliance with Spain. He was badly lodged and treated with contempt, and was not allowed to forward letters to England, but the English victory over the Armada and his own patience secured for English traders exclusive rights of trading on the Volga and their security from the infliction of torture. He returned to England in 1589 in company with Jerome Horsey, and in 1591 he published *Of the Russe Commonwealth*, a comprehensive account of Russian geography, government, law, methods of warfare, Church and manners. Horsey also wrote a narrative of his travels, published in *Purchas his Pilgrimes* (1626). The Russia company were alarmed at the freedom of Fletcher's book, and had it suppressed. In 1856 it was edited in full for the Hakluyt Society.

Fletcher was appointed "remembrancer" to the city of London, and an extraordinary master of requests in 1596, and became treasurer of St. Paul's in 1597. He was saved from imprisonment as surety for his brother's debts, in 1596, by Essex, and was actually imprisoned in 1601, apparently for attributing Essex's disgrace to Raleigh. Fletcher was employed in 1610 to negotiate with Denmark on behalf of the "Eastland Merchants"; he died next year, and was buried on March 11, in London.

The Russe Commonwealth was issued in an abridged form in *Hakluyt's Principal Navigations, Voyages, etc.* (vol. i., p. 473, ed. of 1598), a somewhat completer version in *Purchas his Pilgrimes* (pt. 3, ed. 1625), also as *History of Russia* in 1643 and 1657. Fletcher also wrote *De literis antiquae Britanniae* (ed. by Phineas Fletcher, 1633), a treatise on "The Tartars," printed in *Israel Redux* (ed. by S[amuel] L[ee], 1677), to prove that they were

the ten lost tribes of Israel, Latin poems published in various miscellanies, and *Licia*, or *Poemes of Love in Honour of the admirable and singular virtues of his Lady, to the imitation of the best Latin Poets . . . whereunto is added the Rising to the Throne of Richard the third* (1593). This series of love sonnets, followed by some other poems, was published anonymously. Most critics, with the notable exception of Alexander Dyce (Beaumont and Fletcher, *Works*, i., p. xvi., 1843), have accepted it as the work of Dr. Giles Fletcher on the evidence afforded in the first of the *Piscatory Eclogues* of his son Phineas, who represents his father (Thelgon), as having "raised his rime to sing of Richard's climbing."

See E. A. Bond's Introduction to the Hakluyt Society's edition of *The Russe Commonwealth* (1856); also Dr. A. B. Grosart's prefatory matter to *Licia* (Fuller Worthies Library, Miscellanies, vol. iii., 1871), and to the works (1869) of Phineas Fletcher in the same series. Fletcher's letters relative to the college dispute with the provost, Dr. Roger Goad, are preserved in the Lansdowne mss. (xxiii., art. 18 *et seq.*), and are translated in Grosart's edition. See also H. E. Cory, *Spenser, the School of the Fletchers, and Milton* (Univ. of California Publications, No. 5, 1912).

FLETCHER, GILES (c. 1584–1623), English poet, younger son of the preceding, was educated at Westminster school and Trinity college, Cambridge. In 1603 he contributed a poem on the death of Queen Elizabeth to *Sorrow's Joy*. His great poem of *Christ's Victory* appeared in 1610, and in 1612 he edited the *Remains* of his cousin Nathaniel Pownall. His sermons at St. Mary's were famous. Fuller tells us that the prayer before the sermon was a continuous allegory. He left Cambridge about 1618, and soon after received, it is supposed from Francis Bacon, the rectory of Alderton, on the Suffolk coast. His last work, *The Reward of the Faithful*, appeared in the year of his death (1623).

The principal work by which Giles Fletcher is known is *Christ's Victorie and Triumph, in Heaven, in Earth, over and after Death* (1610). The theme owes something to the *Semaines* of Du Portas, but the devotion, the passionate lyricism and the exquisite vision of paradise is Fletcher's own. The metre is an eight-line stanza owing something to Spenser, of whom, like his brother Phineas, he was a disciple. The first five lines rhyme a, b, a, b, b, and the stanza concludes with a rhyming triplet, resuming the conceit which nearly every verse embodies. Like most amateurs of the conceit, he is sometimes grotesque, but when he forgets his ingenuity he attained a depth of melody that delighted Milton, who followed him to some extent in *Paradise Regained*.

Giles Fletcher's poem was edited (1868) for the *Fuller Worthies Library* (1876) for the *Early English Poets* by Dr. A. B. Grosart, and, with this brother's works, by Prof. Boas (2 vols., 1908–09). It was also reprinted for *The Ancient and Modern Library of Theological Literature* (1888), and in R. Cattermole's and H. Stebbing's *Sacred Classics* (1834, etc.) vol. 20. In the library of King's college, Cambridge, is a ms. *Aegidii Fletcherii versio poetica Lamentationum Jeremiae*, and see H. E. Cory, *Spenser, the School of the Fletchers, and Milton* (Univ. of California Publications, No. 5, 1912).

FLETCHER, JOHN WILLIAM (1729–1785), English divine, was born at Nyon, Switzerland, on Sept. 12, 1729, his original name being DE LA FLÉCHÈRE. He was educated at Geneva for the Church, but went to Lisbon and enlisted. An accident prevented his sailing with his regiment to Brazil, and he went to England, picked up the language, and in 1752 became tutor in a Shropshire family. Here he came under the influence of the new Methodist preachers, and in 1757 took orders, being ordained by the bishop of Bangor. He often preached with John Wesley and for him. Refusing the wealthy living of Dunham, he accepted the humble one of Madeley, where for 25 years (1760–85) he lived and worked with unique devotion and zeal. Fletcher was one of the few parish clergy who understood Wesley and his work, yet he never wrote or said anything inconsistent with his own Anglican position. In theology he upheld the Arminian against the Calvinist position, but always with courtesy and fairness; his resignation on doctrinal grounds of the superintendency (1768–71) of the countess of Huntingdon's college at Trevecca left no unpleasantness. The outstanding feature of his life was a transparent simplicity and saintliness of spirit. Wesley preached his funeral sermon from the words "Mark the perfect man." Southey said that "no

age ever provided a man of more fervent piety or more perfect charity, and no church ever possessed a more apostolic minister." It is said that Voltaire, when challenged to produce a character as perfect as that of Christ, at once mentioned Fletcher of Madeley. He died on Aug. 14, 1785.

Complete editions of his works were published in 1803 and 1836. The chief of them, written against Calvinism, are *Five Checks to Antinomianism*, *Scripture Scales to weigh the Gold of Gospel Truth*, and the *Portrait of St. Paul*. See lives by J. Wesley (1786); L. Tyerman (1882); F. W. Macdonald (1885); J. Maratt (1902); also C. J. Ryle, *Christian Leaders of the 18th Century* (1869).

FLETCHER, PHINEAS (1582–1650), English poet, elder son of Dr. Giles Fletcher, and brother of Giles the younger, noticed above, was born at Cranbrook, Kent, and baptized on April 8, 1582. He was educated at Eton and King's college, Cambridge. His pastoral drama, *Sicelides or Piscatory* (pr. 1631) was written (1614) for performance before James I., but only produced after the king's departure at King's college. He became chaplain to Sir Henry Willoughby, who presented him in 1621 to the rectory of Hilgay, Norfolk, where he married and spent the rest of his life. In 1627 he published *Locustae, vel Pietas Jesuitica*. The *Locusts or Apollyonists*, two parallel poems in Latin and English attacking the Jesuits. An erotic poem, *Brittains Ida* (1628), bearing Spenser's name, is included among his works by Dr. Grosart. In 1632 appeared two theological prose treatises, *The Way to Blessedness* and *Joy in Tribulation*, and in 1633 his *magnum opus*, *The Purple Island*. It included his *Piscatorie Eclogs and other Poetical Miscellanies*. He died in 1650, his will being proved on Dec. 13. *The Purple Island, or the Isle of Man*, is a poem in 12 cantos describing in cumbrous allegory the physiological structure of the human body and the mind of man. The manner of Spenser is preserved throughout, and the chief charm of the poem lies in its descriptions of rural scenery. Some critics see in the allegorist of *The Purple Island* a link between Spenser and Bunyan. The *Piscatory Eclogues* are pastorals the characters of which are represented as fisher boys on the banks of the Cam, and are interesting for the light they cast on the biography of the poet himself (Thyrail) and his father (Thelgon). The poetry of Phineas Fletcher has not the sublimity sometimes reached by his brother Giles. The mannerisms are more pronounced and the conceits more far-fetched, but the verse is fluent, and lacks neither colour nor music.

Editions of his works have been printed by Dr. A. B. Grosart (Fuller Worthies Library, 4 vols., 1869) and Prof. Boas (with those of Giles Fletcher, 2 vols., 1908–09). See also H. E. Cory, *Spenser, the School of the Fletchers, and Milton* (Univ. of California Publications, No. 5, 1912).

FLEURANGES, ROBERT (III.) DE LA MARCK, SEIGNEUR DE (1491–1537), marshal of France and historian, was the son of Robert II. de la Marck, duke of Bouillon, seigneur of Sedan and Fleuranges, whose uncle was William de la Marck, "The Wild Boar of the Ardennes." At the age of ten he was sent to the court of Louis XII., and placed in charge of the count of Angoulême, afterwards King Francis I. He served in Francis's Italian campaigns, and in 1512 the French being driven from Italy, Fleuranges was sent into Flanders to levy a body of 10,000 men, in command of which, under his father, he returned to Italy in 1513, seized Alessandria, but failed to take Novara. In 1515 he distinguished himself at Marignano, where the king knighted him with his own hand. He next took Cremona, and was there called home by the news of his father's illness. In 1519 he was sent into Germany to canvass the electors in favour of Francis I. Fleuranges fought at Pavia (1525), and was taken prisoner with Francis. The emperor, irritated by the defection of his father, Robert II. de la Marck, kept him in prison in Flanders for some years. During this imprisonment he was created marshal of France. In his *Histoire des choses mémorables advenues au règne de Louis XII. et de François I., depuis 1499 jusqu'en l'an 1521*, written in prison, ed. Lambert 1735, also in the *Nouvelle Collection des mémoires pour servir à l'histoire de France* (edited by J. F. Michaud and J. J. F. Poujoulat, series i. vol. v. Paris, 1836 *seq.*), he gives many curious and interesting details of the events he had witnessed. He died at Longjumeau in Dec. 1537.

FLEUR-DE-LIS (Fr. "lilyflower"), an heraldic device, very

widespread in the armorial bearings of all countries, but more particularly associated with the royal house of France. The conventional fleur-de-lis, as Littré says, represents very imperfectly three flowers of the white lily (*Lilium*) joined together, the central one erect, and each of the other two curving outwards. The fleur-de-lis is a common device in ancient decoration, notably in India and in Egypt, where it was the symbol of life and resurrection, the attribute of the god Horus. It is common also in Etruscan bronzes. It is uncertain whether the conventional fleur-de-lis was originally meant to represent the lily or white iris—the flower-de-luce of Shakespeare—or an arrow-head, a spear-head, an amulet fastened on date-palms to ward off the evil eye, etc. In Roman and early Gothic architecture the fleur-de-lis is a frequent sculptured ornament. As early as 1120 three fleurs-de-lis were sculptured on the capitals of the Chapelle Saint-Aignan at Paris. The fleur-de-lis was first definitely connected with the French monarchy in an *ordonnance* of Louis le Jeune (c. 1147), and was first figured on a seal of Philip Augustus in 1180. The use of the fleur-de-lis in heraldry dates from the 12th century, soon after which period it became a very common charge in France, England and Germany, where every gentleman of coat-armour desired to adorn his shield with a loan from the shield of France, which was at first *d'azur, semé de fleurs de lis d'or*. In Feb. 1376 Charles V. of France reduced the number of fleurs-de-lis to three—in honour of the Trinity—and the kings of France thereafter bore *d'azur, à trois fleurs de lis d'or*. Tradition soon attributed the origin of the fleur-de-lis to Clovis, the founder of the Frankish monarchy, and explained that it represented the lily given to him by an angel at his baptism. Whatever be the true origin of the fleur-de-lis as a conventional decoration, it is demonstrably far older than the Frankish monarchy, and history does not record the reason of its adoption by the royal house of France, from which it passed into common use as an heraldic charge in most European countries. An order of the Lily, with a fleur-de-lis for badge, was established in the Roman states by Pope Paul III. in 1546; its members were pledged to defend the patrimony of St. Peter against the enemies of the Church. Another order of the Lily was founded by Louis XVIII. in 1816,

in memory of the silver fleurs-de-lis which the comte d'Artois had given to the troops in 1814 as decorations; it was abolished by the revolution of 1830.

FLEURUS, a village of Belgium, in the province of Henne-gau, 5m. N.E. of Charleroi, famous as the scene of several battles. The first of these was fought on Aug. 19–29, 1622, between the forces of Count Mansfeld and Christian of Brunswick and the Spaniards under Cordovas, the latter being defeated. The second is described below, and the third and fourth, incidents of Jourdan's campaign of 1794, under FRENCH REVOLUTIONARY WARS. The ground immediately north-east of Fleurus forms the battlefield of Ligny (June 16, 1815), for which see WATERLOO CAMPAIGN.

The second battle (for its strategic prologue see GRAND ALLIANCE, WAR OF THE) was fought on July 1, 1690, between 45,000 French under duke of Luxembourg, and 37,000 allied Dutch, Spaniards and Imperialists under George Frederick, prince of Waldeck. The latter had formed up his army between Heppignies and St. Amand in what was then considered an ideal position; a double barrier of marshy brooks was in front, each flank rested

on a village, and the space between, open upland, fitted his army exactly. But Luxembourg, riding up with his advanced guard from Velaine, decided, after a brief survey of the ground, simultaneously to attack the front of the Allies' position, envelop their right flank and turn their left flank by a wide manoeuvre on to their rear, a boldness and breadth of tactical conception which was rare for the age, indeed for any age. The left wing of cavalry was

PLAN OF THE SECOND BATTLE OF FLEURUS, JULY 1, 1690

to move under cover of woods, houses and hollows to gain Wangeries, where it was to connect with the frontal attack of the French centre from Fleurus and to envelop Waldeck's right. Luxembourg himself with the right wing of cavalry and some infantry and artillery made a wide sweep round the enemy's left by way of Ligny and Les Trois Burettes, concealed by the high-standing corn. At 8 o'clock the frontal attack began by a vigorous artillery engagement, in which the French, though greatly outnumbered in guns, held their own, and three hours later Waldeck, whose attention had been absorbed by events on the front, found a long line of the enemy already formed up in his rear. He at once brought his second line back to oppose them, but while he was doing so the French leader filled up the gap between himself and the frontal assailants by posting infantry around Wagnellee, and also guns on the neighbouring hill whence their fire enfiladed both halves of the enemy's army up to the limit of their ranging power. At 1 P.M. Luxembourg ordered a general attack of his whole line. He himself scattered the cavalry opposed to him and hustled the Dutch infantry into St. Amand, where they were promptly surrounded. The left and centre of the French army were less fortunate, and in their first charge lost their leader, de Gournay, one of the best cavalry officers in the service. But Waldeck, hoping to profit by this momentary success, sent a portion of his right wing towards St. Amand, where it merely shared the fate of his left, and the day was decided. Only a quarter of the cavalry and 14 battalions of infantry (English and Dutch) remained intact, and Waldeck could do no more, but with these he emulated the last stand of the Spaniards at Rocroi 50 years before. A great square was formed of the infantry, and a handful of cavalry joined them—the French cavalry, eager to avenge de Gournay, had swept away the rest. Then slowly and in perfect order, they retired into the broken ground above Mellet, where they were in safety. The French slept on the battlefield, and then returned to camp with their trophies and 8,000 prisoners. They had lost some 2,500 killed, the Allies twice as many, as well as 48 guns, and Luxembourg was able to send 150 colours and standards to decorate Notre-Dame. But the victory was not followed up, for Louis XIV. ordered Luxembourg to keep in line with other French armies which were carrying on more or less desultory wars of manoeuvre on the Meuse and Moselle.

FLEURY (ABRAHAM JOSEPH BENARD) (1750–1822), French actor, was born at Chartres on Oct. 26, 1750, and began his stage apprenticeship at Nancy, where his father was an actor at the court of King Stanislaus. He came to Paris in 1778, and almost immediately was made *sociétaire* at the Comédie Française, although the public was slow to recognize him as the greatest comedian of his time. In 1793 Fleury was arrested in consequence of the presentation of Laya's *L'Ami des Lois*, and, when liberated, appeared at various theatres until, in 1799, he rejoined the rehabilitated Comédie Française. He retired in 1818 and died on March 3, 1822.

See J. P. B. Lafitte, *Mémoires de Fleury, de la Comédie Française* (6 vols. 1836–38); *The French Stage and the French People, as illustrated in the Memoirs of M. Fleury* (ed. Theodore Hooke, 2 vols. 1841); J. de Bourgoingue, *Un comédien d'autrefois* (1914).

FLEURY, ANDRÉ HERCULE DE (1653–1743), French cardinal and statesman, was born at Lodève (Hérault) on June

22, 1653, the son of a collector of taxes. Educated by the Jesuits in Paris, he entered the priesthood, and became in 1679, through the influence of Cardinal Bonzi, almoner to Maria Theresa, queen of Louis XIV., and in 1698 bishop of Fréjus. Seventeen years later he became tutor to the king's great-grandson and heir, and in spite of an apparent lack of ambition, he acquired over the child's mind an influence which proved to be indestructible. On the death of the regent Orleans in 1723 Fleury, already 70 years of age, deferred his own supremacy by suggesting the appointment of Louis Henri, duke of Bourbon, as first minister. Fleury was present at all interviews between Louis XV. and his first minister, and on Bourbon's attempt to break through this rule Fleury retired from court. Louis made Bourbon recall the tutor, who on July 11, 1726, took affairs into his own hands, and secured the exile from court of Bourbon and of his mistress Madame de Prie. He refused the title of first minister, but his elevation to the cardinalate in that year secured his precedence over the other ministers. He was naturally frugal and prudent, and carried these qualities into the administration, with the result that in 1738-1739 there was a surplus of 15,000,000 livres instead of the usual deficit. In 1726 he fixed the standard of the currency and secured the credit of the government by the regular payment thenceforward of the interest on the debt. By exacting forced labour from the peasants he gave France admirable roads, though at the cost of rousing angry discontent. During the 17 years of his orderly government the country found time to recuperate its forces after the exhaustion caused by the extravagances of Louis XIV. and of the regent, and the general prosperity rapidly increased. Internal peace was only seriously disturbed by the severities which Fleury exercised against the Jansenists. He imprisoned priests who refused to accept the bull *Unigenitus*, and he met the opposition of the parlement of Paris by exiling 40 of its members.

In foreign affairs his chief preoccupation was the maintenance of peace, which was shared by Sir Robert Walpole, and therefore led to a continuance of the good understanding between France and England. But he reluctantly supported the ambitious projects of Elizabeth Farnese, queen of Spain, in Italy by guaranteeing in 1729 the succession of Don Carlos to the duchies of Parma and Tuscany. Fleury had economized in the army and navy, as elsewhere, and when in 1733 war was forced upon him he was hardly prepared. He was compelled by public opinion to support the claims of Louis XV.'s father-in-law Stanislaus Leszczyński, ex-king of Poland, to the Polish crown on the death of Frederick Augustus I., against the Russo-Austrian candidate; but the despatch of a French expedition of 1,500 men to Danzig only served to humiliate France. Fleury was driven by Chauvelin to more energetic measures; he concluded a close alliance with the Spanish Bourbons and sent two armies against the Austrians. Military successes on the Rhine and in Italy secured the favourable terms of the treaty of Vienna (1735-1738). France had joined with the other powers in guaranteeing the succession of Maria Theresa under the Pragmatic Sanction, but on the death of Charles VI. in 1740 Fleury by a diplomatic quibble found an excuse for repudiating his engagements, when he found the party of war supreme in the king's counsels. After the disasters of the Bohemian campaign he wrote in confidence a humble letter to the Austrian general Königsegg, who immediately published it. Fleury disavowed his own letter, and died a few days after the French evacuation of Prague on Jan. 29, 1743. He had enriched the royal library by many valuable oriental mss., and was a member of the French Academy, of the Academy of Science, and the Academy of Inscriptions.

FLEURY, CLAUDE (1640-1723), French ecclesiastical historian, was born at Paris on Dec. 6, 1640. Educated at the aristocratic college of Clermont (now that of Louis-le-Grand), he was nominated an advocate to the parlement of Paris in 1658,

but nine years later, he turned to theology and by 1672 was in orders. The king entrusted to him the education of the princes of Conti and of the count of Vermandois, one of his natural sons, on whose death in 1683 Fleury received for his services the Cistercian abbey of Loc-Dieu, in Rhodéz. In 1689 he was appointed sub-preceptor of the dukes of Burgundy, of Anjou and of Berry, and thus became intimately associated with Fénelon, their chief tutor. On the completion of the education of the young princes the king appointed him prior of Argenteuil, near Paris (1706), and he resigned that of the abbey of Loc-Dieu. Fleury, who had been made confessor to the young king Louis XV. in 1716, because, as the duke of Orleans said, he was neither Jansenist nor Molinist, nor Ultramontanist, but Catholic, died on July 14, 1723. His great learning was equalled by the modest simplicity of his life and the uprightness of his conduct.

His chief work, the *Histoire ecclésiastique*, which comes down to 1414 and was completed by others down to 1684, has passed through many editions, the first being that of Paris, 20 vols., 1691, Partial Eng. trs., 1842 ff. His other works include:—*Histoire du droit françois* (1674, Eng. trs., 1724), *Moeurs des Israélites* (1681, Eng. trs., 1805); *Moeurs des Chrétiens* (1682, Eng. trs., 1698); *Traité du choix et de la méthode des études* (1686, 2 vols.); *Les Devoirs des maîtres et des domestiques* (1688); his *Catéchisme historique* (1679, Eng. trs., 1726) and the *Institution du droit ecclésiastique* (1687) were put on the Index.

FLEXNER, SIMON (1863-), American pathologist, was born at Louisville (Ky.), on March 25, 1863. After he graduated from the University of Louisville in 1889 he pursued his studies further at Johns Hopkins university and the universities of Strasbourg, Berlin and Prague, and at the Pasteur institute, Paris. He was associate professor and later professor of pathological anatomy at Johns Hopkins during 1889-99, becoming in 1899 professor of pathology at the University of Pennsylvania. In 1903 he was appointed director of the laboratories of the Rockefeller institute for Medical Research, New York. Dr. Flexner became widely known in 1905 for his successful treatment of cerebrospinal fever by the use of a serum, the administration of which reduced the mortality rate from 75% in untreated cases to 25% in cases where the serum was used. He has published numerous monographs, on *The Pathology of Toxalbumin Intoxication*, *Serum Treatment of Epidemic Meningitis* (1917); *Epidemic Poliomyelitis, Epidemiology*.

His brother ABRAHAM FLEXNER (b. 1866) became in 1917, secretary of the General Education Board. His views on education as set forth in *A Modern School* (1916) and *A Modern College* (1923) occasioned much discussion. He wrote also *Prostitution in Europe* (1914) and works on medical education. (See SPINAL MENINGITIS.)

FLICKER, the name given in North America to large, ant-eating woodpeckers of the genus *Colaptes*. Both sexes have a red band on the nape. The golden-winged flicker (*C. auratus*) has the under surface of wings and tail bright, golden yellow; it is found in the South Atlantic States, while a subspecies (*C. A. luteus*) is widely distributed over the Northern States, east of the Rocky mountains. The red-shafted flicker (*C. cafer collaris*) with the under surface of wings and tail red, is found from the eastern slope of the Rocky mountains to the Pacific. A subspecies extends to Alaska. The gilded flicker (*C. chrysoides*) has the lining of wings and tail yellow, but lacks the red nuchal patch; it is found in southern California and Arizona.

FLIEDNER, THEODOR (1800-1864), German Protestant divine and philanthropist, was born on Jan. 21, 1800, at Epstein (near Wiesbaden), and studied at Giessen, Göttingen and Herborn. In 1821 he became pastor of the Protestant church at Kaiserswerth, on the Rhine. During a visit to England in 1823 he made the acquaintance of Elizabeth Fry. The German prisons were then in a very bad state. The prisoners were huddled together in dirty rooms, badly fed, and left in complete idleness. Fliedner applied for permission to be imprisoned for some time, in order to see prison life from the inside. This petition was refused, but he was

allowed to hold fortnightly services in the Düsseldorf prison, and to visit the inmates individually. On June 18, 1826, the first Prison Society of Germany (*Rheinisch-Westfälischer Gefängnisverein*) was founded. In 1833 Fliedner opened in his own parsonage garden at Kaiserswerth a refuge for discharged female convicts. He then turned to the care of the sick poor, and he began a scheme for securing proper training for nurses. In 1836 he began the first deaconess house, and the hospital at Kaiserswerth, the institution which gave Florence Nightingale fruitful ideas on the provision of nursing. By their ordination vows the deaconesses devoted themselves to the care of the poor, the sick and the young; but their engagements were not final—they might leave their work and return to ordinary life if they chose. Fliedner also founded (1835) an infant school, then a normal school for infant school mistresses (1836), an orphanage for orphan girls of the middle class (1842), and an asylum for female lunatics (1847). He assisted at the foundation and in the management of similar institutions, not only in Germany, but in various parts of Europe.

In 1849 he resigned his pastoral charge, and till 1851 travelled over a large part of Europe, America and the East—the object of his journeys being to found “mother houses,” which were to be not merely training schools for deaconesses, but also centres whence other training establishments might arise. He established a deaconess house in Jerusalem, and after his return assisted by counsel and money in the erection of establishments at Constantinople, Smyrna, Alexandria and Bucharest. He founded the Christian house of refuge for female servants in Berlin (connected with which other institutions soon arose) and the “house of evening rest” for retired deaconesses at Kaiserswerth. Fliedner died on Oct. 4, 1864, leaving behind him over 100 stations.

His son FRITZ FLIEDNER (1845–1901), after studying in Halle and Tübingen, became in 1870 chaplain to the embassy in Madrid and founded several philanthropic institutions in Spain. He was also the author of a number of books, among which was an autobiography, *Aus meinem Leben, Erinnerungen und Erfahrungen* (1901).

See G. Fliedner, *Theodor Fliedner, kurzer Abriss seines Lebens und Wirkens* (3rd ed., 1892). See also on Fliedner and his work *Kaiserswerth Deaconesses* (1857); J. S. Howson, *Deaconesses* (1862); E. C. Stephen, *The Service of the Poor* (1871); W. F. Stevenson, *Praying and Working* (1865).

FLIER, a purchase of stock that is known by the buyer to be of a highly speculative nature, and by which he hopes to make a quick turnover at a profit, though realizing that there is also a great possibility of loss. *Taking a fier* is essentially a gamble and is so recognized.

FLIGHT (NATURAL). The flight of birds has been from time immemorial a riddle as well as a source of inspiration. The author of the Proverbs of Solomon describes “the way of an eagle in the air” as “too wonderful” for him; and for many centuries the paradox that a bird could for hours together maintain its motion without a flap of the wing or any appreciable expenditure of energy seemed hopeless of explanation. But though the upward gliding of a vulture until it is almost invisible, or the effortless sailing of an albatross for hundreds of miles over the ocean are obviously marvellous, the ordinary flapping flight of a swift or a pigeon is in reality almost as wonderful. For flapping flight involves a combination of a highly perfected mechanical design of the wings with a motive power of remarkable lightness; and, though men have carried on sailing flight in a motorless aeroplane for hours on end, a motor-driven flapping aeroplane has not been produced.

Gliding, Soaring or Sailing Flight.—For comprehension of the fundamental principles underlying non-flapping flight, we are indebted to the late Lord Rayleigh who in 1883 remarked that “wherever . . . a bird pursues his course for some time without working his wings we must conclude either (1) that the course is not horizontal, (2) that the wind is not horizontal, or (3) that the wind is not uniform.” As we shall see these suggestions lead to the solution of the problem, which, as far as flight inland is concerned, may be exemplified by the behaviour of an ordinary vulture. He weighs about 10 lb., has wings each about 3 ft. long and 1 ft. wide, and, about an hour after sunrise, when he throws

himself off the bough on which he has roosted, he gives the impression of being too heavily loaded for any but the clumsiest of flying. He flaps laboriously uphill, usually in a spiral path, until he has reached a height of 50 or 100 ft. and then a mysterious change begins to show itself; he flaps less and less hard and after a short time starts gliding steadily and majestically upwards in his spiral. After reaching a considerable height, which may be between 500 and 2,000 ft., he has no need of further effort, and seems able to float at will in any direction and at any pace

FIG. 1.—AIR FORCES ACTING ON A WING SHOWING HOW, WHEN MOVING HORIZONTALLY, THE WING EXPERIENCES A VERTICAL LIFT, L, AND A BACKWARD DRAG, D

that he likes until he descends for food or because sunset is approaching.

The details of his flight do not diminish our surprise; for the air in the plains is often so still that there is no suggestion of an up-current sufficient to support a 10 lb. weight, and with the plane of his wings inclined upwards (the forward edge being higher than that in the rear) a vertical up-current would seem to drive him backward, not forward. His continued advance seems inexplicable.

Downhill Gliding Through Still Air.—If a bird is gliding horizontally through still air the resistance of the air must lessen his speed, and on the other hand if he glides steeply downhill he will gain in speed. There must be some slope for which he will neither gain nor lose speed and its inclination is called the “angle of descent.” Much detailed information has been accumulated regarding the forces which act on wings of various cross-sections and on elongated bodies when travelling at different speeds through the air (see AERONAUTICS); and if we have a wing of cross section AB (see fig. 1) travelling in the direction X’OX the air-forces acting on it are equivalent to (1) a resistance or “drag” D backwards in the reversed direction of motion, (2) a lifting force L at right angles to the direction of motion. For a “high velocity” section, the ratio of L : D may reach 17. So when our bird is gliding steadily downhill along a line inclined and to the horizon it is acted on by D, L and its weight W, and we must have

$$\frac{P}{\cos \alpha} = \frac{D}{\sin \alpha} = W$$

Now it may easily be calculated from well-known data that if we construct an artificial bird with rectangular wings of standard section and a torpedo-shaped body all of approximately the actual dimensions, the total weight being that of the bird, its angle of descent will be about 4° or 5°. Further, we habitually see birds in the tropics gliding at a considerable height in all directions without any obvious descent; but we should not observe an angle of descent of 5° under these conditions, and for one who has been able to watch the gliding of kites from a hill it is impossible to believe that their angle of descent is as great as this. Hence, although past measurements of the forces acting upon stuffed birds in wind tunnels have indicated great inferiority by comparison with aerofoils fitted to torpedo-shaped bodies, the ratio of lift/drag in the stuffed birds not exceeding 5, the failure must be explained by the difficulty of preserving the true shape of the wing. Preliminary experiments made at S. Kensington have confirmed this view and from measurements made on living birds in 1920 in Africa, P. Idrac found a lift/drag ratio of about eighteen.

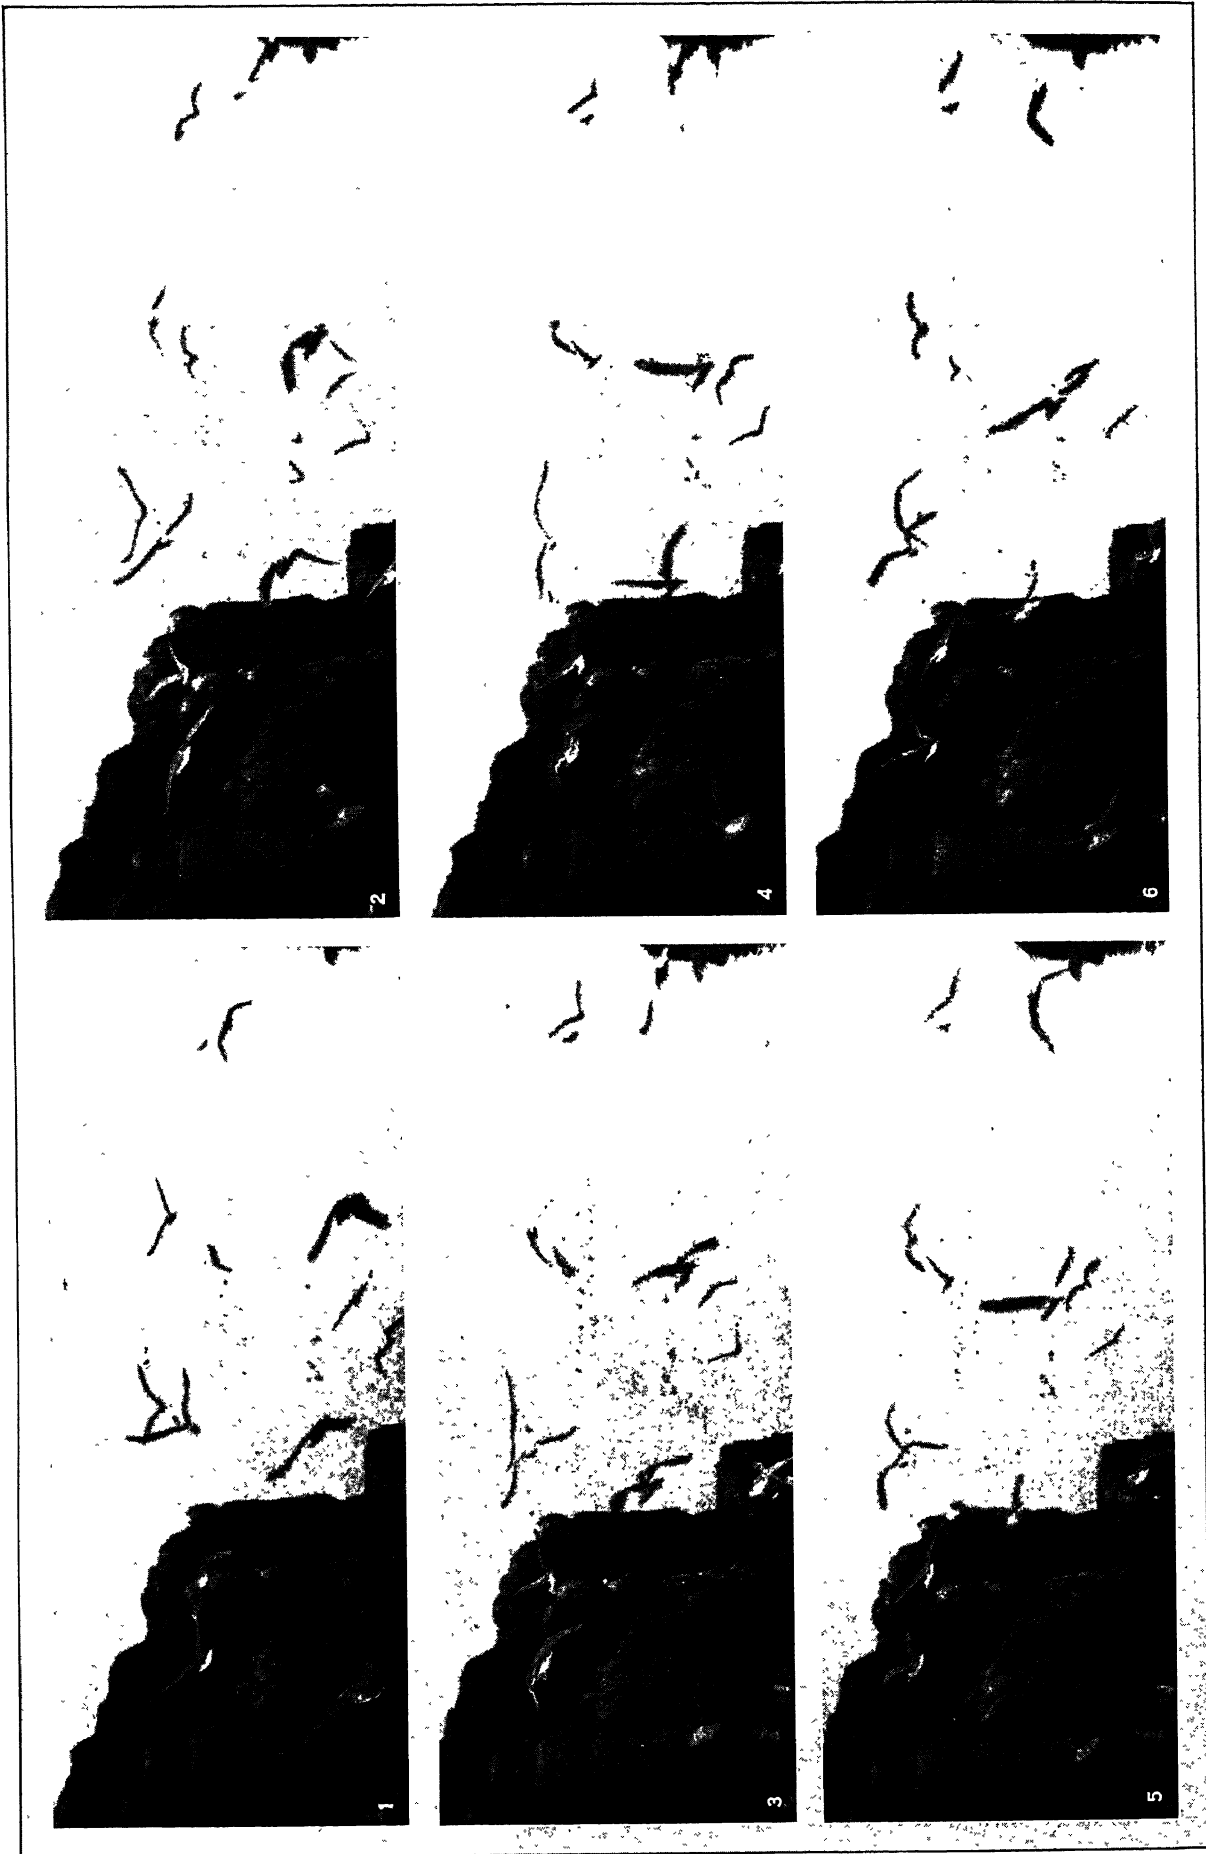

Gliding When There Is an Upward Current of Air.—If a bird whose angle of descent is 1 in 12 is gliding through still air at 18 miles an hour he will be descending at the rate of $\frac{1}{2}$ or $1\frac{1}{2}$ miles an hour; and if there were a column of air ascending at over 1½ m. an hour the bird would climb as long as he kept within it in a spiral path.

Now an ordinary observer has no evidence of such vertical air motion, for near the ground that motion must be negligible; but there is complete proof, both meteorologically and by direct measurement, of its existence. We know that in sunny weather, owing to the overheating of air near the ground, conditions in continental regions in summer in medium latitudes and in the tropics for much of the year are unstable; so that a mass of

WILD SWANS IN STEADY FLIGHT

Series of cinema photographs, showing wing movements of birds in course of flight. The changes can best be observed by following the movements of the two birds at the top of the pictures. The wings are straightened at the end of the upward beat, curved at the end of the downward beat. At the beginning of the upward beat the wings are bent to avoid air resistance; at the beginning of the downward beat the wings are straightened to give maximum driving surface.

KITTIWAKE GULLS IN FLIGHT

BY COURTESY OF THE BRITISH INSTRUCTIONAL FILMS, LTD.

The pictures in the series are timed at equal intervals. By observing the top gull against the dark cliff throughout the series a cycle or flap of the wings can be followed, ending in the rapid upward flick of the wings. 1, beginning of downbeat; 2, 3 & 4, movements in downbeat, showing twist or bend of wings; 5, 6, upbeat, wings raised in preparation for downbeat tips steeply inclined upward

air rising above a heated rock will climb to a considerable height before it cools to the same temperature as the surrounding air and comes to rest. These local upward currents are experienced by meteorological kites and balloons, and their effects are described by aviators as "bumps"; in Egypt, for instance, they extend to heights of 4,000 to 10,000 feet. In addition to large currents there are "small vertical currents" whose bottoms can in many cases be detected "in the vicinity of a town by kites or hawks soaring," and whose vertical speed over hilly country is probably as much as 16 ft. a second. The dependence of soaring flight on vertical currents is also completely confirmed by the observations of Idrac in Senegal.

When a bird of prey is "stooping" at a great speed he bends his wing considerably at the elbow and wrist joints as shown at (a) in fig. 2; when he is gliding and not troubling about climbing the bending is slight as at (b); but when he is trying to ascend all he can do is straighten his wings and spreads out the primary quills (the pinions at the ends of his wings) so that they are separate from each other over a length of about a fifth of the wing; as at (c). Nature obviously attaches some importance to this feature for she employs a special device to increase the separation beyond that due to the mere fan-like spreading of the feathers; she deliberately leaves the primary quills of full width for about half their length and then steps down the width almost to half the previous amount for the outer half of the length of the quill. This feature, sometimes called the "notch" is apparently universal in birds of prey and the device, as a whole, strongly recalls the Handley-Page slotted wing which enables an aeroplane to climb at a much bigger angle of incidence. Thus G. T. Walker reports having seen vultures climbing on an upward current of about 12 ft. a sec., their speed being about 25 ft. a sec. up a slope of about 20° , the inclination of the wings also being 20° . If in fig. 3 $OP=25$ represents the velocity of the bird in space, PN the vertical rate of climb is about 8.5 f.s., so that if $QP=12$ represents the upward velocity of the air, the rate of climb through the ascending air is $NQ=3.5$ f.s. and OQ , the bird's path relation to the air, descends at about 8.5° , so that the real angle of incidence POQ is about 28.5° . At first sight it would seem as if the bird could not possibly maintain its forward motion against the resistance of the air. But if we consider the forces acting—the "lift" L (at right angles to the relative motion and so inclined forwards at 8.5° to the vertical) and the "drag" D —it is clear that the condition for maintenance of the forward motion is that the resultant of L and D shall be forward of the vertical, or that (since $8.5^\circ=7.7^\circ$) the lift shall exceed 7.7 times the drag; this condition is satisfied with a Handley-Page wing.

When an aeroplane is losing pace the pilot is tempted to raise the nose of his machine so as to increase the angle of incidence of the wings and get an adequate lift; but this process checks his pace, and if he is still losing height, it may be that no further increase of the angle of incidence will support the aeroplane. The machine is thus said to "stall," control may be lost and a crash occur. Now at such times a Handley-Page slot is of great value in enabling control to be kept; and as a bird trying to climb fast is probably near the stalling angle very often, the slotted ends of its wings have probably the great advantage of enabling it to maintain control. Vultures when climbing may occasionally be seen to make sudden movement of the wings which ends in a

FIG. 2.—A VULTURE GLIDING ILLUSTRATING THE SHAPE OF WINGS WHEN (A) DESCENDING STEEPLY, (B) GLIDING EASILY AND (C) CLIMBING AS FAST AS POSSIBLE

FIG. 3.—FORCES ON A BIRD GLIDING ON AN ASCENDING CURRENT SHOWING HOW THE BIRD IS DRIVEN FORWARD BY AN ASCENDING CURRENT ALTHOUGH THE UPWARD SLOPE OF ITS WINGS SUGGESTS A BACKWARD FORCE

short downhill path and probably indicates recovery from a difficult situation of this kind.

Gliding (or Sailing) When the Wind Is Not Uniform.—

Lord Rayleigh indicated in general terms the mechanism by which the energy necessary to maintain flight could be derived from the variability of the wind. He pointed out that it is the velocity of the bird relative to the air, not its velocity relative to the ground, which determines the forces acting on it; and the bird can at any time by climbing upwards turn some of the energy of that relative velocity, with comparatively slight loss owing to air resistance, into energy of position; conversely he can with little loss by gliding downhill turn energy of position into velocity relative to the air.

Now if the bird is flying horizontally with relative velocity U , the potential height to which he could climb is $U^2/2g$, where g is the acceleration due to gravity; and if relative to the air he has an acceleration f in the direction of U , U^2 will after an extremely short interval τ become $(U + f\tau)^2$ and will so increase at a rate $2Uf$; hence the potential height will grow at a rate Uf/g . Also as the bird is moving horizontally L the "lift" must be equal to his weight; and if the ratio L/D is k , D will be the weight divided by k ; so as the weight would produce a downward acceleration g , the backward acceleration due to the drag is g/k . Now if the wind is changing in any continuous manner it will have some acceleration where the bird is, which we can call f' , and by steering always so as to meet that acceleration he will secure an acceleration $(f' - g/k)$ through the air and will gain potential height at a rate $U(f' - g/k)/g$ or $U(f'/g - 1/k)$. If the bird does not fly directly against the direction of f' so that there is only a component $-f''$ along his path, f'' must replace f' in this formula.

Now it has long been known that the velocity of the wind is in general far from steady and much light has been gained regarding the gustiness due to eddymotion of the air under various conditions. It has been estimated by Walker that in an ordinarily gusty wind of 22 m. an hour the acceleration due to turbulence is in excess of $2fs$, and for stronger winds proportionally higher. So for a bird with $k=12$, whose angle of descent would be 5° , we must have f/g not less than $\frac{1}{12}$ or f not less than $\frac{2}{3}g$, i.e., $2\frac{2}{3}$. Thus a wind averaging $22 \times 2\frac{2}{3} \div 2$, or, say, 30 m. an hour would enable a bird to keep up its velocity without flapping.

It may be noted that not only do some inland birds of temperate regions, such as rooks, and many sea-birds avail themselves of turbulence for sailing flight, but also tropical birds of prey who usually depend on convection currents. Thus on overcast days when there are not enough upward currents for kites and scavenger vultures to glide they usually remain in their trees; but occasionally a sudden change in the weather will start them gliding in all directions as if aimlessly, or for pleasure; and it would appear that turbulence afforded the explanation. Nonflapping flight is also possible when the wind, though steady, varies from place to place, as when a gull uses the screening of the wind by a vessel to describe circles near its stern.

The principle also has an important application to the gliding or sailing flight of albatrosses and other large sea birds in windy weather away from the influence of ships. It is known that the velocity of the wind must diminish down to the surface of the water owing to the influence of friction at the surface and of eddymotion in the air; so by rising or falling a bird can get into a stronger or weaker current of air. If then he sails uphill against the wind, the air that he meets will be at increasing heights and will have an increasing velocity in the direction opposite to his motion, so that his rate of travel through it will not diminish as it would if the air were stationary; i.e., he will gain potential height. Exactly the same happens if he sails downhill with the wind, which is then decreasing in speed and has an acceleration in the direction opposite to his velocity. The natural way to combine these effects is to describe circles in an inclined plane, always descending when moving to leeward and ascending when moving to windward. It is accordingly interesting that the results of a mission of Idrac to the south seas to study the problem entirely confirmed Rayleigh's ideas. He found (a) that such flight was

only possible for very swift birds, the average speed of the albatross being 72 f.s. or 49 miles an hour; and (b) it needs a minimum wind of 17 f.s. close to the water.

Now the rate of increase of wind with height varies greatly with the conditions; and in the absence of detailed observations close to the surface of the sea we must utilize those over land made by the London Meteorological Office which agree with those at Nauen in giving an excess of 47% in the wind at 50 feet (5 metres) compared with that at $6\frac{1}{2}$ feet (2 metres) above ground. So corresponding to a speed of 24 f.s. at 7ft. we can deduce r , the velocity increase for 1ft. of height, as .26 f.s. Further, it seems that over the sea in high latitudes the reduction of the velocity will not extend so high as over land, and r will be greater. We shall not be very far wrong in taking it as .3 though Idrac's formula leads to only .2.

If the albatross climbs a slope of 1 in 3 at 72 f.s. against the wind his rate of ascent is 24 f.s., so that the increase of the wind in a second is 7.2 f.s. If for simplicity's sake we may treat U as constant in the computation, the rate of gain of potential height $U(f/g - 1/k)$ is 1.6ft. if $k=15$; so he would in 2 seconds of either climb against, or descend with, the wind gain enough energy to take him 116 yards before further thought was necessary. Of course, a greater rate of increase of wind with height, or a greater efficiency of design, would enlarge his powers, but a moderate rate would seem to give an albatross the ability to roam apparently at will. If he describes a circle inclined at 20° with the lowest point to leeward and say 5ft. above the sea, while the highest point is 50ft. above sea, Walker's approximate formula gives a gain of potential height of 13ft. on describing the circle. Reference may also be made to a letter to *Nature* by S. L. Walkden.

Flapping Flight.—Birds differ materially in the details of their flapping, the contrasts between the deliberate beat of a heron, the smooth silent flight of an owl, and the hurried whirr

BY COURTESY OF THE BRITISH INSTRUCTIONAL FILMS, LTD.

FIG. 4-5.—WILD SWANS RISING FROM THE WATER

In this series the swans are seen taking off from the lake. As greater driving power is needed than for steady flight, the wings are more rotated on the up beat and brought more forward on the down beat

of a partridge being conspicuous enough. But the general character of the wing movements is the same; and as there have been differences of opinion, mainly owing to the difficulties of observation, regarding the fundamental facts, it will be useful to refer to the twelve reproductions in Plate I. of wild swans derived from a "slow-motion" cinema film made by British Instructional Films, Ltd. In Plate I., fig. 1, the two top birds are marked (a) and (b), and in fig. 6 will be found diagrams (1) to (12) showing approximately the positions of the wings of bird (a) at instants corresponding with the figures of the plate. In them two features

stand out prominently; (a) the time interval between successive pictures being constant, the time of a down beat is half as long again as that of an upbeat; and (b) though the wings are kept straight during positions 2-6 of a down beat, they are bent during 8-11 of the up-beat, the outer portions remaining almost at the same angle with the horizontal for the time 7-9, and being then lifted with a flick in the second half of the upbeat, 9-11. As may

FIG. 6.—PROFILES OF WINGS DURING A DOWN-BEAT AND AN UPBEAT MADE AT EQUAL INTERVALS SHOW THAT THE UP-BEAT TAKES PLACE MORE RAPIDLY THAN THE DOWN-BEAT, THE OUTER PORTION OF THE WINGS BEING RAISED WITH A FLICK

backwards along the path.

It will be seen that the force L always tends to drive the bird forwards; and as it is much greater than D which tends to retard the forward motion, the outer portion of the wing contributes propulsion. Also both L and D have a downward tendency during the upbeat, though the tendency is upward during the downbeat; so this portion of the wing is of little avail for support. With the inner portion, however, the situation is quite different. Here the slight up-and-down motion is almost cancelled by the slight down-and-up motion of the bird's body, so that the flight is essentially non-flapping; the section of the wing must be adapted for high lift and the angle of incidence is positive so that there is lift all the time.

Reference to fig. 7 will show that the plane of the wing is twisted. Near the top of the up-beat, when the upward flick of the outer portion occurs, the plane of the outer portion at B will be inclined more uphill than of the inner portion at B, but this is not so in the early portion of the upbeat at A and A₁. And during

FIG. 7.—THE ROTATION OF THE WING: (A) OUTER THIRD, (B) INNER THIRD, ILLUSTRATING WHY THE INCLINATION OF THE INNER AND OUTER PORTIONS OF A WING IS NOT SO IN THE EARLY PORTION OF THE UPBEAT AT A AND A₁. AND DURING FLIGHT

the downbeat the outer portions of the wing will be inclined downwards but not the inner portion. These inferences may be verified in the illustration of Plate II. of Kittiwake gulls. In figs. 1, 2 of Pl. II., we have the downbeat of the marked bird with the downward inclined tips seen almost edge on. At the beginning of the upbeat in 15, the inner portions are inclined uphill more than the tips; but in 5, during the flick, the tips are inclined uphill more steeply than the inner portions.

As will be seen from the reproductions, the swans (a) and (b) are ascending, so that their beats must be stronger than if they were flying horizontally; and it is worth while to see what modi-

fications occur when a bird has to exert all his force. In the figures 4-6 we have some wild swans flapping hard to get into the air, that to left in 4 beginning his downbeat; that to right is beginning his upbeat. They have not yet acquired much pace, and are using their feet as well as their wings. It will be seen in 5, that, as far as rotation is concerned, the plane of the wings of one is inclined downhill, while that of the other is uphill, and the reason is that, with a speed insufficient for the inner portion to support the weight by mere gliding, the bird has to adopt an uphill path and aim at more propulsion; so he uses most of the wing as he previously used only the outer portion, and with marked rotation of the type indicated in fig. 8. At the lowest point (see fig. 5) the wings are rather forward, partly in order to avoid the water, but also in order to secure propulsion along a more upward direction.

FIG. 8.—BIRD CLIMBING STEEPLY, SHOWING HOW THE WHOLE WING IS EMPLOYED IN PRODUCING FORWARD DRIVE

The question naturally arises whether a machine fitted with aerofoils of known properties as wings attached to a torpedo-shaped body would support and propel itself in the air if its dimensions and weight were those of a typical bird such as a rook; and the wings were flapped in approximately the same manner. To this Walker, as the result of an approximate computation with a "high lift" inner third of the wings for support and a flat outer third for propulsion, replies "Yes." He also finds that the power requisite compares not unfavourably with that necessary for a screw propeller driving a gliding bird with fixed wings.

Flight by Creatures Other Than Birds.—There is no evidence of the use by these of principles other than those described; and it will therefore suffice to indicate the chief types:—Bats, Flying Lemurs, Flying Squirrels, Flying Phalangids; Pterodactyles (extinct), Flying Lizards (or Dragons), the Flying Snake of Borneo; Flying-fishes, Flying-gurnards, American and African Fresh-water Flying-fishes; Insects.

FLINCK, GOVERT (1615-1660), Dutch painter, born at Cleves in 1615, was sent to study art at Leuwarden, where he boarded in the house of Lambert Jacobszon. Here Flinck was joined by Jacob Backer. Amongst the neighbours of Jacobszon at Leuwarden were the sons and relations of Rombert Ulenburg, whose daughter Saske married Rembrandt in 1634. The pupils of Lambert probably gained some knowledge of Rembrandt by intercourse with the Ulenburgs. Certainly J. von Sandrart, who visited Holland in 1637, found Flinck acknowledged as one of Rembrandt's best pupils, and living habitually in the house of the dealer Hendrik Ulenburg at Amsterdam. For many years Flinck laboured on the lines of Rembrandt, following that master's style in all the works which he executed between 1636 and 1648; then

he fell into peculiar mannerisms by imitating the swelling forms and grand action of Rubens's creations. Finally he sailed with unfortunate complacency into the Dead Sea of official and diplomatic painting. Flinck's relations with Cleves became in time very important. He was introduced to the court of the Great Elector, Frederick William of Brandenburg, who married in 1646 Louisa of Orange. He obtained the patronage of John Maurice of Orange, who was made stadtholder of Cleves in 1649. Flinck was enrolled in 1652 as a citizen of Amsterdam and married in 1656 an heiress, daughter of Ver Hoeven, a director of the Dutch East India company.

The earliest of Flinck's authentic pieces is a likeness of a lady, dated 1636, in the gallery of Brunswick. His first subject picture is the "Blessing of Jacob," in the Amsterdam museum (1638). Both are thoroughly Rembrandtesque in effect. The four "Civic Guards" of 1642, and "The Twelve Musketeers" with their president in an arm-chair (1648), in the townhall at Amsterdam, are fine specimens of composed portrait groups. But the best of Flinck's productions in this style is the "Peace of Münster" in the museum of Amsterdam. Flinck here painted his own likeness to the left in a doorway. The mannered period of Flinck is amply illustrated in the "Marcus Curius eating Turnips before the Samnite Envoys," and "Solomon receiving Wisdom," in the palace on the Dam at Amsterdam. In addition to the foregoing may be noted the "Grey Beard" of 1639 at Dresden, the "Girl" of 1641 at the Louvre, a portrait group of a male and female (1646) at Rotterdam, a lady (1651) at Berlin. Of several pictures which were painted for the Great Elector, Frederick William of Brandenburg, none are preserved except the "Expulsion of Hagar" in the Berlin museum. Flinck died at Amsterdam on Feb. 22, 1660.

FLINDERS, MATTHEW (1774-1814), English navigator, was born at Donington in Lincolnshire on Mar. 16, 1774, and entered the navy in 1789. He served in the "Bellerophon" at Ushant in 1794, and from 1795 to 1799 was engaged in exploration on the Australian coast, including the circumnavigation of Tasmania in 1798. On his return to England he was appointed to the command of an expedition for the thorough exploration of the Australian coasts. The sloop "Investigator" left Spithead on July 18, 1801, and reached Cape Leeuwin on Nov. 6. On his way round the coast he met the French exploring ship "Le Géographe" on Apr. 8, 1802, in what is now Encounter Bay. The narrative of the French expedition claimed discovery of most of the land west of the point of meeting, and the matter was not cleared up till the publication of Flinders' book in 1814.

Flinders reached Port Jackson on May 9, 1802. On July 22 he set out again to complete the circumnavigation of Australia. He examined the Great Barrier Reef and surveyed the gulf of Carpentaria, and then, finding the "Investigator" to be in a leaky state, sailed round the west and south of Australia back to Port Jackson, which he reached on June 9, 1803, after a voyage in which much suffering had been endured by everyone, particularly from scurvy. He left Port Jackson for England in the "Porpoise" which, together with the "Cato," was wrecked on a coral reef, about 800 miles out, on Aug. 17. The officers and men camped on a small sandbank, while Flinders returned to Port Jackson in a six-oared cutter to obtain relief. He got back and took them off on Oct. 8, and on the 11th sailed again in the "Cumberland." Putting in at Mauritius on Dec. 15, he found England and France at war, and his passport from the French government did not cover the "Cumberland." He was detained until June 1810, and reached England in October. His narrative, "*A Voyage to Terra Australis*," was published on July 19, 1814, on which day Flinders died. This work contains very valuable scientific observations, especially with regard to magnetism, meteorology, hydrography and navigation. He seems to have been the first to discover, and correct for, the errors of the compass caused by iron in ships. He also wrote *Observations on the coast of Van Diemen's Land*, etc., and two papers in the *Phil. Trans.* in 1805 and 1806.

See *Proc. R. G. S. Australasia*, South Australia branch, 14 (1912-1913), pp. 48-74; E. Scott, *Life of Captain Matthew Flinders* (Sydney, 1914); G. G. McCrae, in *Victoria Geog. Journal*, 28 (1910-1911), pp. 12-30 and 29 (1912-1913), pp. 1-19.

FLINDER'S BARS, vertical bars of soft iron placed in front of or behind a ship's compass to compensate the disturbing magnetic effects due to the vertical soft iron parts of the ship. Other effects due to soft and hard iron in horizontal and vertical directions are also eliminated by bars or by spheres appropriately placed. (See COMPASS.)

FLINDERS RANGE: see AUSTRALIA.

FLINSBERG, a village of Germany, in the Prussian province of Silesia, on the Queis, at the foot of the Iserkamm, 1,725 ft. above the sea, south of Friedeberg, the terminus station of the railway from Greiffenberg. Pop. (1925) 2,700. It has some manufactures of wooden wares. Flinsberg is celebrated for its chalybeate waters for bathing and drinking, and as a climatic health resort.

FLINT, AUSTIN (1812-1886), American physician, was born at Petersham, Mass., on Oct. 20, 1812, and graduated in medicine at Harvard university in 1833. From 1847 to 1852 he was professor of medicine in Buffalo Medical college, of which he was one of the founders, and in 1852-56 he filled the same chair in the University of Louisville. From 1861 to 1886 he was professor of medicine in Bellevue Hospital Medical college, New York. He wrote many text-books on medical subjects, among these being *Diseases of the Heart* (1859-70); *Principles and Practice of Medicine* (1866); *Clinical Medicine* (1879); and *Physical Exploration of the Lungs* (1882). He died in New York on March 13, 1886.

His son, **AUSTIN FLINT** (1836-1915), who was born at Northampton, Mass., on March 28, 1836, after studying at Harvard and at the University of Louisville, graduated at the Jefferson Medical college, Philadelphia, in 1857. He then became professor of physiology at the University of Buffalo (1858) and subsequently at other centres, his last connection being with the Cornell University Medical college (1898-1906). His *Text-book of Human Physiology* (1876) was for many years a standard book in American medical colleges. He also published an extensive *Physiology of Man* (5 vols., 1866-1874) and other valuable medical works. He died in New York city on Sept. 23, 1915.

FLINT, TIMOTHY (1780-1840), American clergyman and writer, was born of Puritan stock in Reading, Mass., July 23, 1780. He graduated at Harvard in 1800, and after a rather troubled career as Congregational minister in Lunenburg (Mass.), he became a home missionary. He was also for a short period a teacher and a farmer. His observations on the life and manners of the frontier were recorded in a picturesque work, *Recollections of the Last Ten Years Passed in the Valley of the Mississippi* (1826; reprinted in England and translated into French), one of the most valuable accounts of the West at this period. The success of this volume and the failing health of the writer led him to relinquish his more active labours for literary pursuits, and, besides editing the *Western Monthly Review* in Cincinnati (1827-30) and *The Knickerbocker* in New York (1833), he published a number of books, including *Francis Berrian, or the Mexican Patriot* (1826), his best novel; *A Condensed Geography and History of the Western States* (1828); *George Mason, the Young Backwoodsman* (1829); a *Biographical Memoir of Daniel Boone* (1833); and *Indian Wars in the West* (1833). He also edited the *Personal Narrative* (1831) of J. O. Pattie, an adventurer in Mexico and the Far West. Flint died in Reading (Mass.), Aug. 16, 1840, and was buried at Salem.

See the biography *Timothy Flint* (1911) by J. E. Kirkpatrick, which contains a bibliography.

FLINT or FLINTSHIRE (Sir Gallestr), a county of north Wales, the smallest in Wales, bounded north by the Irish sea and the Dee estuary, north-east by the Dee, east by Cheshire, and south-west by Denbighshire. Area, 163,707 acres. Pop. (1931), 112,849. Included in Flint is the detached hundred of Maelor, lying 8 m. S.E. of the main part of the county, and shut in by Cheshire on the north and north-east, by Shropshire on the south, and by Denbighshire on the west and north-west. Structurally the county is dominated by the Clwydian hills running south-south-east to north-north-west. Their western slope to the Vale of Clwyd is steep but the eastern slope over much of the county to the Vale of Dee is less sharp. The Clwydian hills are an uplift with

a Silurian axis and with younger rocks outcropping on either side. Their highest point is Moel Famau (1,820 ft.) on the Flintshire-Denbighshire boundary.

The Silurian strata of the Clwydian hills, mostly of Wenlock age, pass under the Triassic (Bunter) red beds in the Vale of Clwyd. On the eastern flank of the anticlinal axis the Silurian is overlain by Carboniferous rocks, with Triassic deposits eastward in Cheshire. Both for their influence on the physical features and for their economic value they are the most important rocks in the county. A band of Carboniferous limestone passes from Prestatyn on the coast, close by Holywell and through Caerwen: it forms the Halkin mountain (943 ft.) east of Halkin, whence it continues past Mold to beyond the county boundary. Above these beds come the Holywell shales, possibly equivalent to the Pendleside series of Lancashire and Derbyshire, while upon them lies the Gwespys sandstone. Farther to the east the coal measures extend from Talacre through Flint, Northop, Hawarden and Broughton to Hope. The Carboniferous rocks appear again through the intervention of a fault in the neighbourhood of St. Asaph. The Carboniferous mass of the Halkin mountains is separated from the Clwydian hills on the west by the valley of the Alyn and the small tributary of the Clwyd.

The Alyn enters the county near Moel Famau and passes Cilcen and Mold with a section of underground drainage in the Carboniferous limestone near Hesb-Alyn (the drying-up of Alyn), and bends south to Caergwrle, re-enters Denbighshire and joins the Dee. The latter river enters Flintshire near Overton and divides Maelor from Denbigh on the west, then passes Chester and forms the eastern boundary of the county on the north-east. It enters the Irish sea by means of a wide but shallow estuary. The north-eastern part of Flintshire is a low-lying country bordering the Dee Estuary. The low ground extends westwards to the mouth of the Clwyd valley. This has been one of the great "ways" into Wales for many centuries. Short stretches of blown sand occur on the north coast near Rhyl and Talacre.

Archaeology.—Lead and zinc ores have been worked in the Lower Carboniferous rocks in the north of the county, and caves in the same formation known as Cae Gwyn, Gop and Ffynnon Beuno, have yielded remains of Pleistocene mammals. Much boulder clay and glacial drift cover the older rocks on the east and north and in the Vale of Clwyd. The palaeolithic occupation of Cae Gwyn cave is doubtful, though the find of an unpolished stone axe in the Gop cave may mark its occupation in neolithic times. There is little evidence of occupation during the megalithic phase; one dolmen and one stone circle are known, though the standing stones are more numerous on the high ground. A large number of the barrows are round ones belonging for the most part to the Bronze age. In the Late Bronze age the north coast route was apparently open, as was the edge of the forest lands on the eastern slopes of the Clwydian hills. A breastplate of gold now in the British Museum and a gold torque from the parish of Ysceifiog are important finds, as is also the Caergwrle Cup of uncertain age. Hill-forts of the Romano-British period are important, upon the salient height of the Clwydian hills, and modern studies suggest correlation with the Roman trackways and the mineral wealth of the country. A Roman trackway may be traced from south Denbighshire, through Ffrith along the east of the county to Flint, and it then turns westwards to St. Asaph (?Varae).

History.—The post-Roman centuries saw Flintshire under the influence of the Celtic saints, the Saxons and the Northmen. Bangor is-y-coed had become an important ecclesiastical foundation and Bede records its destruction by Aethelfrith about 615. St. Asaph had also begun to gain ecclesiastical supremacy. The Maen Chwyfan in the parish of Whitford is a fine sculptured cross. The great boundary lines known as Offa's and Wat's Dykes played an important part during this period. Recent examination of the remains in Flintshire (see Cyril Fox, "Offa's Dyke. A Field Survey," *Archaeologia Cambrensis*, vol. lxxxi., 1926, etc. sqq.) have shown Offa's dyke to date from the time of the king whose name it bears; the builders used barrows and other prehistoric sites as guide points in the construction. The Flintshire section seems more of a political frontier than a military work for de-

fensive purposes. The mineral deposits of Halkin mountain are cut off from Wales, suggesting that the dominant party in fixing the dyke was on the eastern side. The occupation of the Wirral peninsula by the Danes had also a profound effect on Flintshire, where many of their place-names still survive. The swampy upper section of the Dee estuary was less favourable for their settlement than the better land near the open sea. When the region that is now Flintshire emerged from the troublesome times of the dark ages we find most of it in the Welsh principality of Powys.

Soon after the arrival of the Normans much of the county, particularly the part to the east of Offa's dyke, came under the control of the lordship of Chester.

The centres of control were Hawarden and Rhuddlan where motte and bailey castles were built. It is, however, important to note that the early Norman penetration was confined to the lowlands, while the upland regions remained in the hands of the Welsh chieftains. So strong did the native power become that in the hands of Owain Gwynedd (1135-70) and his grandson Llewellyn ap Iowerth (1198-1240), Welsh influence was dominant in the county. It was with the building of the stone castles of Hawarden, Hope and Mold, in the middle of the 13th century, that Norman influence gained a stronger foothold, while the interesting castle of Ewloe shows a Welsh construction on a Norman model. The final conquest was achieved with the establishment of the great Edwardian fortresses of Rhuddlan and Flint, in 1277, and the town of Flint was definitely planned at the time. Maelor Saesneg was incorporated in the county in 1284. The county contains two mediaeval religious houses—Basingwerk abbey near Holywell, a Cistercian house founded in 1131 or 1132, and the ruins (now incorporated in a farm) of the Dominican friary of Rhuddlan, founded in the 13th century.

The county had associations with England during the Renaissance, and Dr. Morgan, bishop of St. Asaph (1602-04) directed the translation of the Bible into Welsh. Many of the castles were held for the king during the Civil War of the 17th century, but they soon fell into the hands of the parliament and were "slighted." The rise of the great religious denominations in the 18th and 19th centuries caused a profound change in the social life of Wales. Flintshire, as a border county, had early associations with Puritanism and the Independents were strong in the 19th century. The Calvinistic Methodism of the highlands of Denbighshire was not so marked in Flintshire, though the western section of the county was much affected. The county has retained, in certain regions that still remained under the influence of some ancient landed families, a measure of adherence to the Roman Catholic Church.

Agriculture and Industries.—The Vale of Clwyd is well known for its pasture lands. Out of the 163,707 ac. comprising the county, 120,917 were, in 1925, under crops and grass. The amount of arable land was just under a third of this. Oats, turnips and swedes are the chief crops. Stock and dairy farming prospers, native cattle being crossed with Herefords and Downs, native sheep with Leicesters and Southdowns, while the industrial regions of the county are a ready market for meat, butter, cheese, etc.

The mineral wealth of the county seems to have been known from early times. The location of metal mines in Halkin mountain seems to bear some relation to the Romano-British hill-top camps and the Roman trackways, while the mines were of undoubted importance at the time of King Offa. In the 18th and 19th centuries large numbers of Cornish miners settled in the neighbourhood, leaving their trace in many of the present family names. Halkin mountain was a great lead-mining district. Lead is also raised at Mold, Holywell, Prestatyn and Talacre. Zinc, formerly only worked at Dyserth, has increased in output. Copper is also raised at Talargoch. The exploitation of the coalfield during the latter half of the 19th century transformed the eastern half of the county. The collieries began at Llanasa, then run through Whitford, Holywell, Flint, Halkin, Northop, Buckley, Prestatyn and Hawarden (Penarlâg). The use of the coal led to the extension of the local smelting of the iron and lead ore of the district, and from these occupations important chemical works have grown up

at Flint and along the north coast of the county. Alkali works are most important. The limestone is also worked, and there are some coarse-clay potteries. The presence of the coal and the chemical industries, and expanses of relatively cheap sandy soil on the north coast, the whole being in close proximity to the Lancashire textile industries, has made the neighbourhood of Connah's Quay the site of important factories in the artificial silk industry. Rhyl on the north coast is a seaside resort.

Administration and Communications.—There is one municipal borough—Flint (Pop. 7,635). The county is in the North Wales and Chester circuit, the assizes being held at Mold. Flint borough has a separate commission of the peace, but no separate court of quarter sessions. The county has portions in the dioceses of Chester, Lichfield and St. Asaph. It returns one member to parliament; the constituency known as the Flint Boroughs was abolished in 1918. The L.M.S. line from Chester serves the north and east of the county where it is the main line to Holyhead. Another branch from Chester reaches Hope Junction, where it is joined by a line from Wrexham, and proceeds to Mold. The line from Mold proceeds through the centre of the county almost to Caerwys where it enters Denbighshire. Rhuddlan is served by a branch line from Denbigh through St. Asaph, joining the main line near the Clwyd estuary.

FLINT, a municipal borough and county town in Wales, on the Dee estuary, 11½ m. N.W. of Chester by rail. Pop. (1931), 7,635. Flint castle was built on an isolated rock by the river side by Edward I., who made the little settlement that grew beneath the castle a borough. The town received a charter from Edward III. and the Black Prince, as earl of Chester. It was held for the king during the civil war but twice taken, after siege, by the parliament, and finally dismantled in 1647. The town lived on as a country market town and small seaport until the 19th century, when it became associated with the coal and metal industries of the localities; now it has alkali and chemical works.

FLINT, a city of Michigan, U.S.A., on the Flint river, 70m. N.W. of Detroit; the county seat of Genesee county, the third city of the State in size and the second in value of manufactures, and the second of the world in production of automobiles. It is on Federal highways 10 and 23, and is served by the Grand Trunk and the Pere Marquette railways. The population was 91,599 in 1920 (81.6% native white and 129 males to 100 females) and 156,492 in 1930. The area of the city is about 30 sq.m., and the assessed valuation of property in 1927 was \$176,477,939. The State school for the deaf (established 1854) is here. There are 40 public parks, with a total area of over 1,000 acres. Most of the schools, homes, hotels and business buildings have been built since 1900, over half of them since the World War. Since 1917 development has been guided by a city planning board. The present industrial life of Flint centres around the several subsidiaries of the General Motors corporation which have been established in the city since 1904, including the companies making the Buick and the Chevrolet cars, and bodies, springs, spark plugs and other motor accessories. This group of industries employed in 1928 over 47,000 persons. Other large concerns manufacture such contributory articles as carburetors, paints, varnishes and colours, axles and malleable castings. The aggregate output of the factories in 1927 was valued at \$600,355,781.

A trading post was established here, at "the grand traverse of the Flint," in 1819 by Jacob Smith, a fur trader from Detroit; and in 1830 John Todd, a Pontiac storekeeper, bought 785 ac. of land for \$800 as a speculation, settling here with his family. The little village was made the judicial seat of Genesee county in 1835, two years before Michigan became a State, and was incorporated as a city in 1855. In 1860 the population was 2,950. The city grew gradually until 1900, when it had a population of 13,103. The fur trade was followed by lumbering as the dominating industry, and that in turn by the manufacture of wagons, carts, buggies and carriages, and Flint was known as "the vehicle city" long before an automotive vehicle had been made. The automobile industry dates from 1904, when the Buick Motor Company was established. By 1910 the population had jumped to 38,550, almost three times that of 1900; between 1910 and 1920 the increase was

138%, and in the next eight years (using the local estimate of 1928 for the computation) 58% more. Annexations of territory between 1910 and 1925 increased the area 135%. The value of the manufactured products in 1925 was about 18 times the figure for 1909. Postal receipts in 1926 were over 50 times as much as in 1910. The industrial development necessitated a parallel activity in the building of homes, schools, banks, department stores, theatres and office buildings, and in street paving and lighting, expansion of the public utilities, and of the various city services for the protection of life, health and property. The *per caput* expense for the operation and maintenance of the general city departments increased from \$15.10 in 1918 to \$28.19 in 1927.

FLINT (a word common in Teutonic and Scandinavian languages, possibly cognate with the Gr. *πλίνθος*, a tile), in petrology a black, grey or brown form of hydrated silica which has an almost vitreous lustre, and when pure appears structureless to the unaided eye. When unaltered by weathering, it is, in the mass, dark and opaque, but in thin plates or on the edges of splinters, it is pale yellowish or pale grey. Its hardness is greater than that of steel, so that a knife-blade leaves a grey metallic streak across its surface. It is brittle and if finely broken yields angular chips which are used as an abrasive. The fracture is shell-like, and when resulting from a blow, perfectly conchoidal, so that a "cone" or "bulb" of percussion is formed. Under thermal action (heat or frost) shell-like flakes are removed, but the bulb of percussion is absent. Although the flint appears to be homogeneous, experienced flint "knappers," such as those engaged in gun-flint manufacture at Brandon, Suffolk, recognize a "grain" which permits easy flaking in certain directions. For the removal of smaller flakes, pressure from another stone is sufficient.

When flint is examined microscopically, it is usually found to be very finely crystalline and to consist of quartz and chalcedonic silica; some varieties, however, appear to be amorphous, resembling opal. Sponge-spicules and fragments of other organisms, wholly or partially silicified, with retention of their structures, may be present.

In Britain the term flint is restricted to concretionary nodules, veins and tabular masses found in the Chalk (*see* CRETACEOUS), and as pebbles in the gravels, etc., of Tertiary and Quaternary age derived from its erosion. The coarser and less homogeneous similar substance occurring in the older rocks (Carboniferous Limestone, Devonian, Ordovician and pre-Cambrian) is known as *Chert*. Some cherts contain tests of Radiolaria and thus resemble superficially the radiolarian oozes forming in the oceans at the present day.

The principal use to which flint has been put is the fabrication of weapons in Palaeolithic and Neolithic time (for which *see* FLINTS). The making of gun-flints may be regarded as a survival of this industry. The rounded beach-pebbles of flint from the South Coast of England and the north of France are used for ball-mills in which pottery-materials, sand, etc., are finely ground. Chert-slabs from the Carboniferous and Cretaceous rocks are used similarly in pan-mills. Ground flint is used as a source of silica in glazes and pottery, and as an abrasive. Its use in glass (*e.g.*, for *flint-glass*) has long been abandoned. The use of flint-gravels for road-mending, is now confined to by-roads.

(P. G. H. B.)

FLINT-LOCK: *see* GUN.

FLINTS. The term "Flints" is popularly used to denote implements made by men of the Stone Age, since in Europe flint and flinty materials were frequently used for that purpose.

Flint is a hydrated silica containing a varying amount of water loosely held in combination. When pure it is translucent, but impurities render it opaque and coloured, commonly either black or brown. Irregular flint nodules occur native in horizontal bands in chalk. Their origin is not clearly understood. In some cases it is undoubtedly due to marine organisms, such as sponges which, requiring silica for their growth, secrete it from the water.

Under certain imperfectly understood conditions the water in the flint seems to dry out, leaving on the exposed surface a thin film of white silica; this is known as the patina. When thick it gives a quite white appearance; when very thin the colour of the

unchanged flint underneath shows through, so that a black flint will have a blue appearance. Flint itself is impervious to moisture, but the patina is porous. Thus when patinated flint occurs in gravels containing iron salts a yellow staining, producing the well-known ochreous patina, results. Patinated flint embedded in peats also gets stained in a characteristic manner. Other varieties of staining called by fanciful descriptive names are often due to the patina occurring in patches; thus we have the "toad-belly"

patina found in certain gravel pits in East Anglia. Originally the patinated surface is matt, but where the object has been rolled to some extent in soft sands or loams it becomes polished and lustrous. The thickness of the patina skin is partly a question of the length of time during which the weathering process has operated but it naturally depends on local conditions.

Flints are fractured easily and evenly in three ways, by percussion, by pressure, and by temperature changes.

BY COURTESY OF THE METROPOLITAN MUSEUM OF ART

FLINT IMPLEMENTS OF THE OLD STONE AGE

The discovery of artificially chipped flint in soil belonging to the Palaeolithic epoch has enabled science to trace, with firmer conviction, the history of man back to that period

more or less sharply defined shoulder at the junction of the two. The cap which comes off naturally shows a hollow corresponding to these cones; this is known as the negative cone. If the blow be delivered on the margin of the block a flake comes off showing a swelling near the point of impact. This is the so-called bulb of percussion; it is a partially formed cone. Around this bulb curved lines often appear on the flake, the concavity being always towards the apex of the bulb. This is important, as it sometimes happens in the case of an implement that the bulb has been removed subsequently; but it is still possible to tell from these curved lines the direction from which the blow originally came. When the blow has been particularly intense, lines of fracture radiating from the point of impact also appear on the surface of the flake. They form radii to the curved lines. A small flake scar known as an *écaillure* is often seen on the surface of the bulb. This is not due to an attempt by prehistoric man to get rid of the bulb, but appears under certain conditions when a flake is struck off.

When a piece of flint is struck the force of the blow rapidly diminishes as it penetrates the dense medium. Should there be sufficient energy the fracture set up by the blow, especially if it is struck diagonally outwards near the edge, will go right through the flint, a flake being removed. In this case the new flake-scar forms a clean angle where it meets the original surface of the flint. Should the blow be directed inwards, however, and only penetrate a short way into the flint the shattering will cause a fragment to break off which leaves ridges where the two surfaces meet. The first method is known as "feather-edge" flaking, the second as "resolved" or "step" flaking. Both were used as secondary working to toughen an edge and it is important to differentiate between the two, as "resolved" flaking is especially common in certain prehistoric cultures. In nature percussion flaking takes place by torrent action, where materials are hurled together, the result being chipping in all directions (flint thus knocked about shows innumerable minute incipient cones of percussion); by sea action, where not only is beach material hurled by the waves against larger fixed rocks and so chipped indiscriminately, but also is sucked back by the waves, so that any chance lump of flint embedded in the beach becomes in time much chipped in one direction by the passing pebbles; by ice action in glaciated regions.

Pressure Flaking.—This method of flaking flint was employed by prehistoric man and is still used by many primitive peoples, such as the aborigines of Australia. The aborigine takes a flake and, using the sole of his foot as a tough anvil, presses off little flakes along the margin, wherever he requires a sharp edge or desires to remove material. When a large flake is thus removed a bulb of pressure corresponding to the bulb of percussion appears, but it is, as a rule, considerably flatter. Usually flakes removed by pressure are small and scalelike. The resulting flake scar shows a large number of curved lines like those round a bulb of percussion but generally rather flatter and closer together; the consequent reflection and refraction of light give a characteristic glassy or waxy appearance to an unpatinated pressure-flaked surface. In nature pressure-flaking results from the differential movement of gravels containing a large number of pebbles, such movement being often due to the slipping of a gravel bed down the side of a valley or the caving-in of a gravel bed owing to the solution of some underlying limestone deposit by underground streams. Thus pebbles get forced against one another; and in the latter case especially the pressure tends to come all from one direction, and so definite trimmed edges are produced.

Temperature Changes.—Flint is a very poor conductor of heat but it expands with a rise of temperature. If then the exterior is rapidly heated accommodation with the interior has to take place and there results a series of fractures. In this case no bulb of any sort occurs, but the fractured surface is covered with irregular closed rings. This method has been rarely used by man; but thermal fractures, as they are often called, naturally caused by daily and seasonal changes in temperature, are of common occurrence. Frost action is especially characteristic. As a rule the surface of the flint becomes pitted and covered, as it were, with small hemispherical depressions. Under certain circumstances, too, prismatic bars of flint are found, the formation of these being analogous to that of the prismatic columns occurring in basalt. This is commonly known as "starch" fracture. At first sight these prismatic bars of flint might be taken for cores from which long narrow flakes had been removed. The complete absence of any bulb, coupled with an appearance characteristic of a thermally fractured surface but difficult to describe, at once distinguishes the two.

Mr. Reid Moir has attempted, by studying microscopically fractured surfaces of the flint, to distinguish between the various methods just described. With regard to the appearance of percussion and pressure-flaked surfaces, a rough analogy may be made respectively with the surface of an apple cut by a knife, which is smooth, and that of an apple broken between the two hands, which is rougher and more hackly. No results, of course, can be obtained where the surfaces have been subsequently patinated.

It has become desirable to find criteria which will demonstrate whether a chipped object has been fashioned by man or by nature. As noted previously, when nature chips flint, whether by percussion or pressure, the direction of the blow or pressure comes either from one or an infinite number of directions. What nature cannot do is to apply blows or pressure in two or three definite directions more or less at right angles to one another. Thus it is difficult for nature to knock off a flake and then trim one of the edges, an action involving two directions of blows; and it is almost impossible to invoke nature as the agent if we find a specimen showing also a "prepared" platform on which the blow making the original flake had been struck, thus involving blows from yet a third definite direction. Nor would it have been more possible for nature to achieve this result did we postulate, as might more probably be the case, that the direction of the blows remained constant and that the object itself was revolved once or twice through 90° while receiving the blows.

Of course prehistoric man did not only make his tools of flint, chalcedony, chert, and other flintlike materials which furnish a sharp but brittle working-edge; any kind of fine-grained rock was utilized. In these latter materials the fracture phenomena are similar to those of flint but are far less in evidence and much more difficult to identify. Such rocks, too, fracture irregularly,

and it was not till Neolithic man adopted a grinding and polishing technique that a sharp regular edge was obtainable which had the added virtue of being tough.

Typology (*q.v.*) enables the prehistorian to group the various tools of the Stone Age into families according to their purposes or significant characteristics. The following is a summary of the more important of these tool families.

Coups de poing (sometimes called hand-axes or bouchers).—Originally pear-shaped, boldly flaked, and with irregular edges; later they become flatter and finer. An oval form also develops. In the latter case the edge shows the "S" twist characteristic of the Acheulean culture, where the top part of the tool is, as it were, slightly rotated upon the bottom half. The coup de poing family is especially characteristic of Lower Palaeolithic cultures.

Scrapers.—The essential feature of the scraper is its sharp, convex edge. The chief varieties are side-scrapers, end-scrapers on blades or flakes, round-scrapers and core-scrapers. Side-scrapers generally show the characteristic "resolved" flaking and belong to the Mousterian culture: the other varieties are post-Mousterian. A special kind of core-scraper, in which the flakes removed are narrow and flat and rise fanwise to a well defined keel, is known as the keeled or *tarté*-scraper. It is a characteristic tool of the Middle Aurignacian culture, when such a fluting technique was common.

Awls.—A true awl has a point prepared by careful trimming all round. Pseudo-awls which have the point trimmed only half-way round, the under surface remaining a part of the general flake surface, are, however, common.

Points.—These form a varied family comprising a number of related types and others the connection of which is more obscure. Some types were doubtless used as lance-heads, *e.g.*, the Mousterian Point and the Solutrean Laurel and Willow leaves, others, such as an important series which grade from what are known as Audi Points to Gravette Points were probably pointed knife blades. They have the side of the blade opposite the working edge blunted. This series enables us to subdivide the Aurignacian period into a number of stages.

Pigmy Tools.—The pigmy family includes several distinct types which are named, according to their shape, lunates, crescents, triangles, trapezes, and pigmy scrapers. They are linked together by the fact that they formed the sharp working edges of finished tools, being hafted in various ways into handles made from some other material. The chipping seen on them is generally intended to blunt the edge which is actually to be hafted lest it should cut into or split the haft. Pigmies are found all over the world during widely different periods; they do not necessarily all belong to the same culture.

Celts.—The Celt family is characteristic of Neolithic times, and a grinding and polishing technique is often employed in their manufacture. The original type when chipped only is not unlike the coup de poing at first view. But the carefully prepared sharp, convex working edge is at the broad end of the tool. Two evolutionary series can be determined—one North European, the other West European. In the former the sides of the tool become squared and finally the upper and under surfaces become flat, a section through the tool being rectangular. In the latter the round squat original type becomes flatter and more chisel-like.

Arrow-heads.—Many varieties of arrow-heads are known, some with wings and a central tang, others with wings or tang only; some again are lozenge or leaf shaped. Not only can an evolutionary series be to some extent determined, but certain types only occur commonly in definite areas.

Bone tools, found associated with stone tools during certain periods, can also be classed into families. Harpoons for example form an important evolutionary series, starting with a primitive form where the barbs are hardly detached from the stem and developing through the detached single-barbed varieties to the double-barbed specimens. This series is important for subdividing the Magdalenian culture. Other important bone families are lance-heads, needles, and polishers.

See W. J. Sollas, *Ancient Hunters* (3rd ed., 1924), pp. 78 *et seq.*; M. C. Burkitt, *Prehistory* (2nd ed., 1925), chap. iv. (M. C. B.)

FLOAT, the action of moving on the surface of water, or through the air. The word is used of a wave, or the flood of the tide, river, backwater or stream, and of any object floating in water, as a mass of ice or weeds; a movable landing-stage, a flat-bottomed boat, or a raft, or, in fishing, of the cork or quill used to support a baited line or fishing-net. It is also applied to the inflated organ by means of which certain animals, such as the "Portuguese man-of-war," swim, to a hollow metal ball or piece of whinstone used to regulate the level of water in a tank or boiler, and to a piece of ivory in the cistern of a barometer. "Float" is also the name of one of the boards of a paddle-wheel or water-wheel.

The word also denotes a low, broad cart for carrying heavy weights, and a platform on wheels used for shows in a procession. The term is applied to various tools, especially to trowels used in plastering. It is also used of a dock where vessels may float, as at Bristol, and of the trenches used in "floating" land. In geology and mining, loose rock or ore brought down by water is known as "float," and in tin-mining it is applied to a large trough used for the smelted tin. In weaving the word is used of the passing of weft threads over part of the warp without being woven in with it, also of the threads so passed. In the United States a voter not attached to any party and open to bribery is called a "float" or "floater."

FLOATING ASSETS: *see* CURRENT ASSETS.

FLOATING BATTERY: *see* MONITOR.

FLOATING DEBT. This term is usually applied to that form of National Debt which consists of very short term obligations, such as Treasury Bills and loans from the State or Central Bank (*see* NATIONAL DEBT) in Great Britain and on the Continent, and as Treasury notes and Certificates of Indebtedness in the United States. Floating Debt is normally contracted in order to cover a temporary deficiency of revenue for current requirements, and is the opposite of funded, or long term, debt, but the difference in the floating and funded debt is not always clearly defined.

In normal times a Floating Debt for any large amount is to be avoided. By the very fact of its short-dated character, it is usually held not by investors, but by bankers, large corporations, and money markets, and when outstanding in large amounts may weaken the power of the central banking institution to control local money conditions. Not infrequently, too, when Floating Debt takes the form of direct borrowing from the State or central banking institution, actual inflation is caused. Britain's maximum period of inflation, consequent on the World War, coincided with the creation of Treasury Bills of over £1,200,000,000 with large borrowings at the Bank of England on Ways and Means advances. France also affords a classic example of the extraordinary dimensions to which floating indebtedness can grow, the total of the Floating Debt having risen in 1926 to 132,000,000,000 francs.

The British Floating Debt normally takes the form of Treasury Bills of 3 months' currency, and of Ways and Means advances from the Bank of England anticipating revenue later. This is convenient both for the Treasury and the Money Market, and has been adopted by some of the Empire Governments, but to a less extent in foreign countries. In the United States it was only in June 1929 that an Act was passed authorising the issue of Treasury Bills on comparable lines. These issues supplement the previous American system of short-term financing by means of 3 to 12 months' Treasury Certificates issued and maturing on quarterly tax-payment dates.

The expression Floating Debt is also used in the case of large mercantile and industrial undertakings as a term for distinguishing trade debts and debts borrowed from banks for temporary purposes from debts incurred by the issue of bonds. (A. W. K.)

FLOATING DOCK: *see* DOCKS, FLOATING.

FLOCK. 1. (A word found in O.E. and O.Norw., from which come the Danish and Swedish words, and not in other Teutonic languages), originally a company of people, now mainly, except in figurative usages, of certain animals when gathered together for feeding or moving from place to place. For birds it is chiefly used of geese; and for other animals most generally of sheep and goats.

It is from the particular application of the word to sheep that "flock" is used of the Christian Church in its relation to the "Good Shepherd," and also of a congregation of worshippers in its relation to its spiritual head.

2. (Probably from the Lat. *flocus*, but many Teutonic languages have the same word in various forms), a tuft of wool, cotton, or similar substance. The name "flock" is given to a material formed of wool or cotton refuse, or of shreds of old woollen or cotton rags, torn by a machine known as a "devil." This material is used for stuffing mattresses or pillows, and also in upholstery. The name is also applied to a special kind of wall-paper, which has an appearance almost like cloth, or, in the more expensive kinds, of velvet. It is made by dusting on a specially prepared adhesive surface finely powdered fibres of cotton or silk. The word "flocculent" is used of many substances which have a fleecy or "flock"-like appearance, such as a precipitate of ferric hydrate.

FLODDEN or FLODDEN FIELD, near the village of Braxton, in Northumberland, England (10m. N.W. of Wooler), the scene of a famous battle fought on Sept. 9, 1513, between the English and the Scots. On Aug. 22 a great Scottish army under King James IV. had crossed the border. For the moment the earl of Surrey (who in King Henry VIII's absence was charged with the defence of the realm) had no organized force in the north of England, but James wasted much precious time among the border castles, and when Surrey appeared at Wooler, with an army equal in strength to his own, which was now greatly weakened by privations and desertion, he had not advanced beyond Ford Castle. The English commander promptly sent in a challenge to a pitched battle, which the king, in spite of the advice of his most trusted counsellors, accepted. On Sept. 6, however, he left Ford and took up a strong position facing south, on Flodden Edge. Surrey's reproaches for the alleged breach of faith, and a second challenge to fight on Millfield Plain were this time disregarded. The English commander, thus foiled, executed a daring and skilful march round the enemy's flank, and on the 9th drew up for battle in rear of the hostile army. It is evident that Surrey was confident of victory, for he placed his own army, not less than the enemy, in a position where defeat would involve utter ruin. On his appearance the Scots hastily changed front and took post on Braxton Hill, facing north. The battle began at 4 P.M. Surrey's archers and cannon soon gained the upper hand, and the Scots, unable quietly to endure their losses, rushed to close quarters. Their left wing drove the English back, but Lord Dacre's reserve corps restored the fight on this side. In all other parts of the field, save where James and Surrey were personally opposed, the English gradually gained ground. The king's corps was then attacked by Surrey in front, and by Sir Edward Stanley in flank. As the Scots were forced back, a part of Dacre's force closed upon the other flank, and finally Dacre himself, boldly neglecting an almost intact Scottish division in front of him, charged in upon the rear of King James's corps. Surrounded and attacked on all sides, this, the remnant of the invading army, was doomed. The circle of spearmen around the king grew less and less, and in the end James and a few of his nobles were alone left standing. Soon they too died, fighting to the last man. Among the ten thousand Scottish dead were all the leading men in the kingdom of Scotland, and there was no family of importance that had not lost a member in this great disaster. The "King's Stone," said to mark the spot where James was killed, is at some distance from the actual battlefield. "Sybil's Well," in Scott's *Marmion*, is imaginary.

FLODOARD (894-966), French chronicler, was born at Eprenay, and educated at Reims in the cathedral school which had been established by Archbishop Fulcon (822-900). As canon of Reims, and favourite of the archbishops Herivaues (d. 922) and Seulfus (d. 925), he occupied while still young an important position at the archiepiscopal court, but was twice deprived of his benefices by Heribert, count of Vermandois, on account of his steady opposition to the election of the count's infant son to the archbishopric. Upon the final triumph of Archbishop Artold in 947, Flodoard became for a time his chief adviser, but withdrew to a monastery in 952, and spent the remaining years of his life

in literary and devotional work. His history of the cathedral church at Reims (*Historia Remensis Ecclesiae*) is one of the most remarkable productions of the 10th century. Flodoard had been given charge of the episcopal archives, and constructed his history out of the original texts, which he generally reproduces in full, the documents for the period of Hincmar being especially valuable. The *Annales* which Flodoard wrote year by year from 919 to 966 are doubly important, by reason of the author's honesty and the central position of Reims in European affairs in his time. Flodoard's poetical works are of hardly less historical interest. The long poem celebrating the triumph of Christ and His saints was called forth by the favour shown him by Pope Leo VII., during whose pontificate he visited Rome, and he devotes fourteen books to the history of the popes.

Flodoard's works were published in full by J. P. Migne (*Patrologia Latina*, vol. 135); a modern edition of the *Annales* is the one edited by P. Lauer (Paris, 1906). For bibliography see A. Molinier, *Sources de l'histoire de France* (No. 932).

FLOE, a sheet of floating ice detached from the main body of polar ice, and of less extent than the field of "pack" ice, which is a compacted mass of greater depth drifting frequently under the influence of deep currents, while the floe is driven by the wind.

FLOGGING has been one of the most universally utilized methods of punishing public crimes, as well as a means of preserving family, domestic, military and academic discipline. In the Mosaic code flogging was prescribed as punishment for crime. Down to about 1800 imprisonment was not common as a mode of punishing crime, and not until the 19th century was imprisonment gradually substituted for corporal punishment. Flogging is still frequently employed, being legal in Delaware, Canada, Great Britain and some Continental and Asiatic lands as a punishment for certain crimes, chiefly assault, robbery and rape. As late as 1920 the British Parliament legalized the use of the "cat-o'-nine-tails" in flogging those convicted of robbery. Where flogging was forbidden as a method of punishing criminals its use was often continued within the prisons as a method of enforcing penal discipline. Prison investigations have indicated that flogging as a method of disciplining convicts has not yet disappeared from prison systems. Exponents of severity in dealing with convicts are found urging the revival of flogging in the United States. Slaves were frequently flogged to death when they were sufficiently numerous so that they had little pecuniary value. The flogging of negro slaves in the southern United States prior to the Civil War was exaggerated in Abolitionist literature, inasmuch as the negro slaves were too valuable to have their efficiency reduced by over severe punishment.

The instruments and methods of flogging have varied greatly. In maintaining discipline in the home and school sticks, rods, straps, whips and other handy objects have been informally drafted into service. In punishing criminals and maintaining discipline in army and naval circles the lash, with a variety of ingenious elaborations, has dominated. One of the most popular refinements of brutality with the lash has been the so-called "cat-o'-nine-tails." This gained the name because this flogging device was constructed of nine knotted cords or thongs of rawhide attached to a handle. Even more effective in producing pain and ultimately death is the Russian knout. This is an instrument constructed of a number of dried and hardened thongs of rawhide interwoven with wire, the wires often being hooked and sharpened on the end so that they tear the flesh when the blow is delivered. Severe punishment with the knout means death almost invariably. A particularly painful, though not so deadly, type of flogging is the peculiarly Oriental custom known as the bastinado, or blows delivered upon the soles of the feet with a light rod or a knotted cord or lash. In the period before the reaction set in against corporal punishment, flogging was executed with great brutality. The backs of the condemned were frequently cut in strips and blood gushed freely from the wounds. Not infrequently salt was thrown upon the bleeding backs to increase the pain. With the use of the knout pieces of flesh are literally torn from the back as the hooked points are extracted.

With a growing consciousness that punishment is not so much

a deterrent to crime as had been supposed, flogging, as a general practice, has been abandoned. Modern psychiatry and genetic psychology have shown the dangers inherent in flogging children, in that such procedure may develop inhibitions, antipathies and neurotic traits likely to undermine the whole mental and nervous system of the child.

FLOOD, HENRY (1732–1791), Irish statesman, son of Warden Flood, chief justice of the king's bench in Ireland, was educated at Trinity college, Dublin, and at Christ Church, Oxford. He entered the Irish parliament for Kilkenny in 1759, and immediately began the creation of an opposition in that corrupt body and the education of public opinion in the country. The English government was driven by his efforts to pass the Octennial bill, limiting the duration of parliament to 8 years (there had been no legal limit except that of the reigning sovereign's life), and, during the viceroyalty of Lord Townshend to mitigate the practice of allowing crown patronage to be dispensed by the owners of parliamentary boroughs. The growth of an independent spirit in the Irish House was shown in 1769, when a money bill was sent over by the privy council in London for acceptance by the Irish House of Commons. It was rejected on the ground that the bill had not originated in the Irish House. Parliament was peremptorily prorogued, and a recess of 14 months was employed by the government in securing a majority by the most extensive corruption. Nevertheless when parliament met in Feb. 1771 another money bill was thrown out on the motion of Flood; and the next year Lord Townshend, the lord-lieutenant whose policy had provoked this conflict, was recalled. The struggle was the occasion of a publication, famous in its day, called *Baratariana*, to which Flood contributed a series of powerful letters after the manner of Junius, one of his collaborators being Henry Grattan.

Flood was now in a position such as no Irish politician had previously attained. Under parliamentary conditions that were exceedingly unfavourable, and in an atmosphere charged with corruption, venality and subservience, he had created a party before which ministers had begun to quail, and had inoculated the Protestant constituencies with a genuine spirit of liberty and self-reliance. Lord Harcourt, who succeeded Townshend as viceroy, saw that Flood must be conciliated at any price; accordingly, in 1775, he received a seat in the privy council and the office of vice-treasurer with a salary of £3,500 a year. Flood may reasonably have held that he had a better prospect of advancing his policy by the leverage of a ministerial position than by means of any opposition party he could hope to muster in an unreformed House of Commons. The result, however, was that the leadership of the national party passed from Flood to Grattan, who entered the Irish parliament in the same session that Flood became a minister.

Flood continued in office for nearly seven years. During this long period he necessarily remained silent on the subject of the independence of the Irish parliament, and had to be content with advocating minor reforms as occasion offered. But in 1778 the creation of a volunteer force to defend Ireland against a possible invasion by France, which had become the ally of the revolted American colonies, changed the Irish situation. A Volunteer Convention, formed with all the regular organization of a representative assembly, but wielding the power of an army, began menacingly to demand the removal of the commercial restrictions which were destroying Irish prosperity. Under this pressure the government gave way; the whole colonial trade was in 1779 thrown open to Ireland for the first time, and other concessions were also extorted. Flood, who had taken an active though not a leading part in this movement, now at last resigned his office to rejoin his old party. He found to his chagrin that he was eclipsed by Grattan. But though Flood had lost control of the movement for independence of the Irish parliament, the agitation, backed as it now was by the Volunteer Convention and by

increasing signs of popular disaffection, led at last in 1782 to the concession of the demand, together with a number of other important reforms (*see* GRATTAN, HENRY).

No sooner, however, was this great success gained than a question arose—known as the Simple Repeal controversy—as to whether England, in addition to the repeal of the Acts on which the subordination of the Irish parliament had been based, should not be required expressly to renounce for the future all claim to control Irish legislation. This dispute led to the rupture of friendship between Flood and Grattan, each of whom assailed the other with unmeasured but magnificently eloquent invective in the House of Commons. Flood's view prevailed—for a Renunciation Act such as he advocated was ungrudgingly passed by the English parliament in 1783—and for a time he regained popularity at the expense of his rival. Flood next (Nov. 28, 1783) introduced a reform bill, after first submitting it to the Volunteer Convention. The bill, which contained no provision for giving the franchise to Roman Catholics—a proposal which Flood always opposed—was rejected, ostensibly on the ground that the attitude of the volunteers threatened the freedom of parliament. The volunteers carried a loyal address to the king, moved by Flood. The convention then dissolved, though Flood had desired, in opposition to Grattan, to continue it as a means of putting pressure on parliament for the purpose of obtaining reform.

In 1783 Flood purchased a seat for Winchester in the English House of Commons from the duke of Chandos, and for the next seven years he was a member at the same time of both the English and Irish parliaments. He reintroduced, but without success, his reform bill in the Irish House in 1784; supported the movement for protecting Irish industries; but short-sightedly opposed Pitt's commercial propositions in 1785. He remained a firm opponent of Roman Catholic emancipation, even defending the penal laws on the ground that after the Revolution they "were not laws of persecution but of political necessity"; but after 1786 he does not appear to have attended the parliament in Dublin. In the House at Westminster, where he refused to enrol himself as a member of either political party, he disappointed the expectations aroused by his achievements in Dublin. At the dissolution in 1790 he lost his seat in both parliaments, and he then retired to Farnley, his residence in county Kilkenny, where he died on Dec. 2, 1791.

When Peter Burrowes, notwithstanding his close personal friendship with Grattan, declared that Flood was "perhaps the ablest man Ireland ever produced, indisputably the ablest man of his own times," he expressed what was probably the general opinion of Flood's contemporaries. Grattan never lost his respect for Flood and said that he was the best tempered and the most sensible man in the world. In his youth he was genial, frank, sociable and witty; but in later years disappointment made him gloomy and taciturn. As an orator he was less polished, less epigrammatic than Grattan; but a closer reasoner and a greater master of sarcasm and invective. Personal ambition often governed his actions, but his political judgment was usually sound; and it was the opinion of Bentham that Flood would have succeeded in carrying a reform bill which might have preserved Irish parliamentary independence if he had been supported by Grattan and the rest of his party in 1783. Though he never wavered in loyalty to the British crown and empire, Ireland never produced a more sincere patriot than Henry Flood.

See Warden Flood, *Memoirs of Henry Flood* (1838); Henry Grattan, *Memoirs of the Life and Times of the Right Hon. H. Grattan* (5 vols., 1839-46); Charles Phillips, *Recollections of Curran and some of his Contemporaries* (1822); *The Irish Parliament 1775*, from an official and contemporary manuscript, edited by William Hunt (1907); W. J. O'Neill Daunt, *Ireland and her Agitators*; Lord Mountmorres, *History of the Irish Parliament* (2 vols., 1792); W. E. H. Lecky, *History of England in the Eighteenth Century* (8 vols., 1878-90); and *Leaders of Public Opinion in Ireland* (enlarged edition, 2 vols., 1903); F. Hardy, *Memoirs of Lord Charlemont* (1812), especially for the volunteer movement.

FLOOD, an overflow of water; an expanse of water submerging land; a deluge, hence "the flood" (*see* DELUGE, THE). In the sense of "flowing water," the word is applied to the inflow of the tide, as opposed to "ebb" (O.E. *flōd*).

FLOOD CONTROL: *see* RIVER ENGINEERING.

FLOOD PLAIN, the land-form term for a plain made of sediment deposited by a river. When the gradient of a river becomes very slight, it is unable to carry all the material brought downstream and consequently the lower valley becomes filled with alluvial deposits; in times of flood the river torrent tears off and transports an unusually large quantity of sediment; in the flooded lower valley the rush of water is checked, and the stream in consequence drops its extra load. These flood plains are sometimes of great extent. That of the Mississippi below Ohio has an occasional width of 80 m. with a total area estimated at 50,000 sq.m. Flood plains may be caused by a graded river meandering from side to side, and thus widening its valley and ultimately covering the widened valley with sediment. Any sudden increase in the river's velocity and volume such as by cutting into another stream (piracy) or by cutting through a barrier near its head waters, may result in a flood plain. Any obstruction across a river's course, such as a band of hard rock, or ice flow, may form a flood plain behind it, but it is most commonly found in the lower reaches of such large rivers as the Rhine, Nile or Mississippi, where there are occasional floods and usually large amounts of sediment. The flood-plain is usually bounded by levees (*q.v.*). Sections of the Missouri flood plain made by the United States Geological Survey show a great variety of material of varying depths and of varying coarseness, from heavy gravel through fine sand, to fine silt, and it is probable that any section of such an alluvial plain would show similar deposits.

The flood plain during its formation is characterized by marshes, meandering or anastomosing streams, ox-bow lakes and bayous (*q.v.*), and is occasionally completely drowned. When the drainage system is entirely diverted owing to any cause, the flood plain may become a smooth area of great fertility, similar in appearance to the floor of an old lake, from which it differs, however, inasmuch as it is not quite flat. It has a gentle slope along the original down-stream course, and also usually from the edges towards the centre.

FLOOR, the lower horizontal surface of a room; used, also, almost interchangeably with storey (*q.v.*), to designate the different levels or planes of rooms, one above the other, as ground floor, first floor, etc. Floors were, at first, simply of tamped earth (beaten down), covered with textiles or skins; later, all types of stone pavings were introduced; in Roman times floors of cement or *terrazzo* (small pieces of marble imbedded in cement) were common, as well as mosaic and marble floors, often of great richness. During the middle ages the use of tiles for floors increased; they seem to have been the rule in the great churches. Wooden floors appear early, especially in domestic work and in buildings of many storeys (where their support by wooden beams is a simple matter). At the present time wooden floors are usually double (*see* BUILDING; CARPENTRY; MOSAIC).

FLOOR-CLOTH, a generic term applied to a variety of materials used in place of carpets for covering floors, and known by such trade names as kamptulicon, oil-cloth, linoleum, corticine, cork-carpet, etc. Kamptulicon was patented in 1844 by E. Galloway, but did not attract much attention till about 1862. It was essentially a preparation of indiarubber masticated up with ground cork, and rolled out into sheets between heavy steam-heated rollers, sometimes over a backing of canvas. Owing to its expensiveness, it has given place to cheaper materials serving the same purpose. Oil-cloth is a coarse canvas which has received a number of coats of thick oil paint, each coat being rubbed smooth with pumice stone before the application of the next. Its surface is ornamented with patterns printed in oil colours by means of wooden blocks. Linoleum (*linum*, flax, *oleum*, oil), patented by F. Walton in 1860 and 1863, consists of oxidized linseed oil and ground cork. These ingredients, thoroughly incorporated with the addition of certain gummy and resinous matters, and of pigments such as ochre and oxide of iron as required, are pressed on to a rough canvas backing between steam-heated rollers. Patterns may be printed on its surface with oil paint, or by an improved method may be inlaid with coloured composition so that the colours are continuous through the thickness of the linoleum, instead of being on the surface only, and thus do not disappear. (*See* LINOLEUM.)

FLOOR TRADERS, members of a (especially the New York) stock exchange who buy and sell securities for their own account and who do not conduct transactions for clients. They are to be distinguished from the commission brokers whose exclusive function is to trade for the accounts of clients. Floor traders are often known as *Room traders*.

FLOQUET, CHARLES THOMAS (1828-1896), French statesman, was born at St. Jean-Pied-de-Port (Basses-Pyrénées) on Oct. 2, 1828. He was called to the bar in 1851, and made his name by his fearless attacks on the government in a series of political trials. When the tsar Alexander II. visited the Palais de Justice in 1867, Floquet was said to have confronted him with the cry "Vive la Pologne, monsieur!" He delivered a scathing indictment of the Empire at the trial of Pierre Bonaparte for killing Victor Noir in 1870, and took part in the revolution of Sept. 4. In 1871 he was elected to the national assembly by the department of the Seine. During the Commune he formed the *Ligue d'union républicaine des droits de Paris* to attempt a reconciliation with the government of Versailles. He was imprisoned for a short time after the fall of the Commune. Floquet edited the *République française*, was president of the municipal council, and entered the Chamber of Deputies in 1876. In 1885 he succeeded M. Brisson as president of the chamber. On the fall of the Tirard cabinet in 1888 he became president of the council and minister of the interior in a radical ministry pledged to secure the revision of the constitution. Heated debates in the chamber during the Boulangist agitation culminated on July 13 in a duel between Floquet and Boulanger in which the latter was wounded. In Feb. 1889 the government fell on the question of revision, and in the new chamber of November Floquet was re-elected to the presidential chair. Implicated in the Panama scandals he lost the presidency of the chamber in 1892, and his seat in the house in 1893, but in 1894 was elected to the senate. He died in Paris on Jan. 18, 1896.

See *Discours et opinions de M. Charles Floquet*, ed. A. Faivre (1885).

FLOR, ROGER DI, a military adventurer of the 13th-14th century, was the second son of a falconer in the service of the emperor Frederick II., who fell at Tagliacozzo (1268), and when eight years old was sent to sea in a galley belonging to the Knights Templars. He entered the order and became commander of a galley. At the siege of Acre by the Saracens in 1291 he was accused and denounced to the pope as a thief and an apostate, was degraded from his rank, and fled to Genoa, where he began to play the pirate. Roger then entered the service of Frederick, king of Sicily, who gave him the rank of vice-admiral. At the close of the war, in 1302, as Frederick was anxious to free the island from his mercenary troops (called *Almúgavares*), whom he had no longer the means of paying, Roger induced them under his leadership to seek new adventures in the East, in fighting against the Turks, who were ravaging the empire. The emperor Andronicus II. accepted his offer of service; and in September 1303 Roger with his fleet and army arrived at Constantinople. He was adopted into the imperial family, was married to a grand-daughter of the emperor, and was made grand duke and commander-in-chief of the army and the fleet. After some weeks lost in dissipation, intrigues and bloody quarrels, Roger and his men were sent into Asia, and after some successful encounters with the Turks they went into winter quarters at Cyzicus. In May 1304 they again took the field, and relieved Philadelphia, then invested and reduced to extremities by the Turks. But Roger determined to found in the East a principality for himself. He sent his treasures to Magnesia, but the people slew his Catalans and seized the treasures. He besieged the town, but was repulsed. Being recalled to Europe, he settled his troops in Gallipoli and other towns, and visited Constantinople to demand pay for the *Almúgavares*. Dissatisfied with the small sum granted by the emperor, he plundered the country and carried on intrigues both with and against the emperor, receiving reinforcements all the while from all parts of southern Europe. Roger was now created Caesar, but shortly afterwards the young emperor Michael Palaeologus, not daring to attack the fierce and now augmented bands of adventurers, invited

Roger to Adrianople, and there contrived his assassination and the massacre of his Catalan cavalry (April 4, 1306). His death was avenged by his men in a fierce and prolonged war against the Greeks.

See Moncada, *Expedición de los Catalanes y Aragoneses contra Turcos y Griegos* (Paris, 1840).

FLORA, Italian goddess of flowers, later identified with the Greek Chloris. Her festival at Rome, the Floralia, instituted 238 B.C. by order of the Sibylline books and at first held irregularly, became annual after 173 B.C. It lasted six days (April 28-May 3), the first day being the anniversary of the foundation of her temple. It included theatrical performances characterized by licentiousness. She herself is an original Roman goddess (*indiges*), for she has a flamen (Ovid, *Fasti*, v. 183 *et seq.*; Tacitus, *Annals*, ii. 49).

The term "flora" is used in botany collectively for the plant-growth of a district.

FLOREAL. The name given to the eighth month of the year introduced into the French Republican calendar in 1793. It extended from April 20 to May 19. See CALENDAR.

FLORE AND BLANCHEFEUR, a 13th-century romance. This tale, generally supposed to be of oriental origin, relates the passionate devotion of two children, and their success in overcoming all the obstacles put in the way of their love. The romance appears in differing versions in French, English, German, Swedish, Icelandic, Italian, Spanish, Greek and Hungarian, but the French version of the tale is the most widespread. The various forms of the tale receive a detailed notice in E. Hausknecht's version of the 13th-century Middle English poem of "Floris and Blanchefleur" (*Samml. eng. Denkmäler*, vol. v., 1885). Floire, the son of a Saracen king of Spain, is brought up in constant companionship with Blanchefleur, the daughter of a Christian slave of noble birth. Floire's parents send the boy away at 15 and sell Blanchefleur to foreign slave-merchants. Floire traces her to the tower of the maidens destined for the harem of the emir of Babylon, into which he penetrates concealed in a basket of flowers. The lovers are discovered, but their constancy touches the hearts of their judges. They are married, and Floire returns to his kingdom, when he and all his people adopt Christianity. Of the two 12th-century French poems (ed. Edelstand du Ménil, 1856), the one contains the love story with few additions, the other is a romance of chivalry containing the usual battles, single combats, etc. Two lyrics based on episodes of the story are printed by Paulin Paris in his *Romancero français* (1883). The English poem renders the French version without amplifications; its author has less sentiment than his original, and less taste for detailed description. The similarity between the story of Floire and Blanchefleur and *Aucassin and Nicolette* (q.v.) has been repeatedly pointed out, and they have even been credited with a common source.

See also edition by I. Bekker (1844); the Swedish version by G. E. Klemming (1844); the 13th-century version of Konrad Fleck, *Flore and Blanschefur*, ed. E. Sommer (Leipzig, 1846); also H. Sundmacher, *Die altfr. und mittelhochdeutsche Bearbeitung der Sage von Flore et Blanschefur* (Göttingen, 1872); H. Herzog, *Die beiden Sagenkreise von Flore und Blanschefur* (1884); edition by E. Hausknecht (1885); *Zeitschrift für deut. Altertum* (vol. xxi.) contains a Rhenish version; the Scandinavian *Flores Saga ok Blankiflur*, ed. E. Kölbing (Halle, 1896). The English poem was also edited by Hartschorne (*English Metrical Tales*, 1829), by Laing (Abbotsford Club, 1829) and by Lumly (Early Eng. Text. Soc., 1866, re-edited G. H. McKnight, 1901). J. Reinhold, *Floire et Blanchefleur* (1906) suggests a parallelism with the story of Cupid and Psyche.

FLORENCE, WILLIAM JERMYN (1831-1891), American actor, of Irish descent, whose real name was Bernard Conlin, was born on July 26, 1831, at Albany, N.Y., and first attracted attention as an actor at Brougham's Lyceum in 1851. Two years later he married Mrs. Malvina Pray Littell (d. 1906), in association with whom, until her retirement in 1889, he won all his successes, notably in Benjamin Woolf's *The Mighty Dollar*, said to have been presented more than 2,500 times. In 1856 they had a successful London season, Mrs. Florence being one of the first American actresses to appear on the English stage. His last appearance was with Joseph Jefferson (with whom he had maintained a successful partnership), on Nov. 14, 1891, as Ezekiel Homespun in *The Heir-at-law*, and he died on Nov. 18 in Phila-

delphia.

FLORENCE OF WORCESTER (d. 1118), English chronicler, was a monk of Worcester, who died, as we learn from his continuator, on July 7, 1118. Beyond this fact nothing is known of his life. He compiled a chronicle called *Chronicon ex chronicis* which begins with the creation and ends in 1117. The basis of his work was a chronicle compiled by Marianus Scotus, an Irish recluse, who lived first at Fulda, afterwards at Mainz. Marianus, who began his work after 1069, carried it up to 1082. Florence supplements Marianus from a lost version of the English Chronicle, and from Asser. He is always worth comparing with the extant English Chronicles; and from 1106 he is an independent annalist, dry but accurate. Either Florence or a later editor of his work made considerable borrowings from the first four books of Eadmer's *Historia novorum*. Florence's work is continued up to 1141 by a certain John of Worcester, who wrote about 1150. John is valuable for the latter years of Henry I. and the early years of Stephen. He is friendly to Stephen, but not an indiscriminate partisan.

The first edition of these two writers is that of 1592 (by William Howard). The most accessible is that of B. Thorpe (Eng. Hist. Soc., 2 vols., 1848-49); but Thorpe's text of John's continuation needs revision. Thorpe gives, without explanations, the insertions of an ill-informed Gloucester monk who has obscured the accurate chronology of the original. Thorpe also prints a continuation by John Taxter (died c. 1295), a 13th-century writer and a monk of Bury St. Edmunds. Florence and John of Worcester are translated by J. Stevenson in his *Church Historians of England*, vol. ii. pt. i. (1853); T. Forester's translation in Bohn's *Antiquarian Library* (London, 1854) gives the work of Taxter also.

FLORENCE (Ital. *Firenze*, Lat. *Florentia*), formerly the capital of Tuscany, now the capital of a province of the kingdom of Italy, and the eighth largest city in the country. It is situated 43° 46' N., 11° 14' E., on both banks of the river Arno, which here flows through a broad fertile valley enclosed between spurs of the Apennines. The soil is very fertile; wheat, Indian corn, olives, vines, fruit trees of many kinds cover both the plain and the surrounding hills; the chief non-fruit-bearing trees are the stone pine, the cypress, the ilex and the poplar, while many other varieties are represented. The gardens and fields produce an abundance of flowers which justify the city's title of *la città dei fiori*.

Public Buildings.—Of the very numerous Florentine churches the Duomo (Santa Maria del Fiore) is the largest and most important, founded in 1298 on the plans of Arnolfo di Cambio, completed by Brunelleschi, and consecrated in 1436; the façade, however, was not finished until the 19th century; it was begun in 1875 on the designs of De Fabris and unveiled in 1888. Close by the Duomo is the no less famous Campanile built by Giotto and adorned with exquisite bas-reliefs. Opposite is the Baptistery built by Arnolfo di Cambio in the 13th century on the site of an earlier church, and adorned with beautiful bronze doors by Ghiberti in the 15th century. The Badia, Santo Spirito, Santa Trinita, Santa Croce, Santa Maria Novella, San Lorenzo, are a few among the famous and beautiful churches of Florence. The streets and the piazze of the city are celebrated for their splendid palaces, formerly, and in many cases even to-day, the residences of the noble families of Florence. Among others we may mention the Palazzo Vecchio, the seat of the government of the Republic and now the town hall, the Palazzo Riccardi, the residence of the Medici and now the prefecture, the palaces of the Strozzi, Antinori (one of the most perfect specimens of Florentine *quattrocento* architecture, now the seat of the British Institute founded by the British Government in 1918), Pitti (the Royal Palace), Davanzati, Corsini, etc. The palace of the Arte della Lana or guild of wool merchants, tastefully and intelligently restored, is the headquarters of the Dante Society, and many important monuments, such as the cloister of Santa Maria Novella, the Church of San Miniato, the Houses of the Alighieri family, etc., have been beautifully restored to their ancient splendour.

Libraries.—Florence possesses five important State libraries besides a number of private or circulating collections. The *Biblioteca Nazionale*, formed from the union of the Magliabechi library with the Palatine and opened in 1747, contains 650,000

printed volumes, 800,000 pamphlets, over 9,000 prints and drawings (including 284 by Albrecht Dürer), 21,000 portraits, 3,847 maps, 3,575 incunabula, 20,000 mss. and 40,000 letters. The *Biblioteca Marucelliana* founded in 1752, contains 200,000 books including 700 incunabula, 17,000 engravings and 1,550 manuscripts; it is chiefly remarkable for its collection of illustrated works and art publications. The *Biblioteca Mediceo-Laurenziana*, formed from the collections of Cosimo the Elder, Piero dei Medici and Lorenzo the Magnificent, was first constituted as a public Library in Florence by Clement VII. who charged Michelangelo to construct a suitable edifice for its reception. This was opened to the public by Cosimo I. in 1571. The printed books it contains are only 11,000 in number, but are almost all of the highest rarity and interest, including 242 incunabula of which 152 are *éditiones principes*. It is however the precious collection of mss. amounting to 9,693 articles, including a number of richly ornamented codices of great beauty and costliness, which gives its chief importance to this world famous library. The *Biblioteca Riccardiana*, founded in the 16th century by Romolo Riccardi, contains 3,905 mss., 33,000 volumes and 650 incunabula, chiefly relating to Florentine history. The *Biblioteca Universitaria*, founded in recent years, is rapidly increasing owing to the generosity of many professors who bequeath their collections of books to the University; it contains over 300,000 books mostly of academic character. Among the other libraries is the famous *Gabinetto Vieusseux*, now belonging to the Comune, which contains over 400,000 volumes. The libraries of the *British Institute* and the *Institut Français*; the *Philosophical Library*; and the fine collections at the *German Institute of Art*, at the *Academy of Fine Arts* and at the *Musical Institute*. The State Archives are among the most complete in Italy, and contain over 450,000 *filze* and *registri* and 126,000 charters, covering the period from 726 to 1856.

Galleries and Museums.—Few cities are as rich as Florence in collections of works of artistic and historic interest, although the great majority of them belong to a comparatively limited period, from the 13th to the 16th century. The chief Art Galleries are the Uffizi, the Pitti and Accademia. The two former are among the finest in the world, and are filled with masterpieces by Raphael, Botticelli, the Lippi, Ghirlandaio, Perugino, Andrea del Sarto, Titian and many other Florentine, Umbrian, Venetian, Dutch and Flemish artists, as well as numerous admirable examples of antique, mediæval and Renaissance sculpture. The Pitti collection is in the Royal Palace, formerly the residence of the grand dukes, and connected with the Uffizi Gallery by means of a covered passage across the Ponte Vecchio. There is a splendid museum of mediæval and Renaissance antiquities in the Bargello, the ancient palace of the Podestà, itself one of the finest buildings in the city; among its many treasures are works of Donatello, Ghiberti, Verrocchio and other sculptors, and large collections of ivory, enamel and bronze ware. The Museum of St. Mark, once a monastery, should be mentioned as containing the most complete collection of Fra Angelico's works, besides authentic relics of Savonarola. The Opera del Duomo contains models and pieces of sculpture connected with the cathedral. The Etruscan museum, greatly enlarged in these last few years, deserves a special mention as being the finest in the world. The *Egyptian museum*, the *gallery of tapestries*, the *Bardini gallery*, the *Stibbert museum*, the *Corsini Palace gallery*, the *Medici Chapel at San Lorenzo*, the *frescoes of Benozzo Gozzoli in the Riccardi Palace*, the *Cenacolo of Andrea del Castagno*, the *Michelangelo Museum*, the *museum of natural history*, are all important.

Administration.—Florence is the capital of a province of the same name, and the central government is represented by a prefect (*prefetto*), while local government is carried on by a *podestà* appointed by the government. The city is the seat of a higher Court of Appeal, besides the ordinary civil and military tribunals. It is the headquarters of an army corps, and an archiepiscopal see. Florence which has always been and still is the intellectual centre of Italy, is particularly fortunate from the point of view of education. The University, formerly *Istituto di Studi Superiori e di Perfezionamento*, which was given the university status in 1924, comprises the Faculties of Literature and

Philosophy, Medicine, Law, Mathematics and Natural Sciences, with 1,300 students in all. The original *Studio Fiorentino* was founded in the 14th century, and acquired considerable fame as a centre of learning under the Medici, enhanced by the presence in Florence of many learned Greeks who had fled from Constantinople after its capture by the Turks (1453). The revival of classical studies on scientific principles in modern Italy may be said to have begun in Florence, and great activity has also been displayed in reviving the study of Dante, Dante lectures being given regularly by scholars and men of letters from all parts of the country in the large hall above the church of Or San Michele as in the middle ages, under the auspices of the *Società Dantesca*. Palaeography, history and Romance languages are among the other subjects to which special attention is given. Other very important Institutes are: the *Istituto di Scienze Sociali*, particularly intended for diplomatic training; the Institute of Economics, the Academy of Fine Arts, the Conservatoire of music, the Agricultural Institute, the Institute of Forestry and the Training School for women.

Several of the Florence hospitals are of great antiquity, the most important being that of Santa Maria Nuova, which, founded by Folco Portinari, the father of Dante's Beatrice, has been thoroughly renovated according to modern scientific principles.

Population, Commerce and Industry.—The total population of Florence in June 1928, including foreigners, was 269,450. Florence is the centre of a large and fertile agricultural district, and does considerable business in wine, oil and grain, and supplies the neighbouring peasantry with goods of all kinds. There are no important industries, except a few flour-mills, some glass works, iron foundries, a motor car factory, straw hat factories, and power-houses supplying electricity for lighting and for the numerous tram cars. There are, however, some artistic industries in and around the city, of which the most important is the Ginori-Richard porcelain works, and the Cantagalli majolica works. Another very important source of revenue is the so called "tourist industry," which in late years has assumed immense proportions.

(L. V.)

HISTORY

Florentia was founded considerably later than Faesulae (Fiesole), which lies on the hill above it. Tacitus mentions it, and Florus describes it as one of the *municipia splendidissima*. A bishop of Florence is mentioned in A.D. 313. The first event of importance recorded is the siege of the city by the Goths, A.D. 405, and its deliverance by the Roman general, Stilicho. We find the Longobards in Tuscany in 570, and mention is made of one *Gudibrandus Dux civitatis Florentinorum*, which suggests that Florence was then the capital of a duchy.

Guelphs and Ghibellines.—Under the Carolingian emperors, Tuscany was a march or margraviate, which, in 1054, passed to the famous countess Matilda, daughter of Boniface of Canossa. In the Wars of the Investitures Matilda was on the papal (Guelph) side against the emperor and the faction afterwards known as Ghibelline (see GUELPHS AND Ghibellines), and she herself often led armies to battle. While she presided at the courts of justice in the name of the empire, she was assisted by a group of great feudal nobles, judges, lawyers, etc., who formed, as elsewhere in Tuscany, the *boni homines* or *sapientes*. The citizens found themselves in opposition to the nobility of the hills around the city, Teutonic feudatories of Ghibelline sympathies, who interfered with their commerce, and they began to form themselves into groups and associations, which were the germs of the *arti* or guilds.

After the death of Countess Matilda in 1115 the *grandi* or *boni homines* continued to rule, but in the name of the people—a change which marks the foundation of the commune. After 1138 the *boni homines* began to be called *consules*, while the population was divided into the *grandi* or *delle torri*, i.e., the noble families possessing towers, and the *arti* or industrial and merchant guilds. At first the *consules* were chosen by the *grandi* and assisted by a council of 100, in which the *arti* were predominant. In 1125 Fiesole was sacked and destroyed, but the feudal nobles

of the *contado* (surrounding country), protected by the imperial margraves, were still powerful. The Florentines waged war against the Alberti family, whose castles they destroyed, and fought successfully against the powerful Counts Guidi. Frederick Barbarossa, however, elected emperor in 1152, made his authority felt in Tuscany, and appointed one Welf of Bavaria as margrave, and a *potestas* or *podestà* who resided at San Miniato was appointed to represent the emperor and exercise authority in the *contado*. From the end of the 12th century the *podestà* was always a foreigner. In the meantime Florence had already become an important industrial and banking centre.

The work of crushing the nobles of the *contado* and of asserting the city's position among rival communes continued. The tumults against the Paterine heretics (1244–45), among whom were many Ghibelline nobles, indicate a successful Guelphic reaction; but, when civil war broke out, Frederick of Antioch, imperial vicar in Tuscany, and natural son of Frederick II., entered the city with 1,600 German knights, the Ghibellines triumphed again, and in 1249 the Guelph leaders were driven into exile—the first of many instances in Florentine history of exile *en masse* of a defeated party.

Comune and Popolo.—The Ghibellines being unable to maintain their supremacy, the city came to be divided into two almost autonomous republics, the *comune* headed by the *podestà*, and the *popolo* headed by the *capitano* and militarily organized into 20 companies; the central power was represented by 12 elders. At this time the *podestà's* palace (the Bargello) was built, and the gold florin was first coined and soon came to be accepted as the standard gold piece throughout Europe. But, although greatly strengthened, the Guelphs were not wholly victorious, and in 1251 they had to defend themselves against a league of Ghibelline cities (Siena, Pisa and Pistoia) aided by Florentine Ghibellines. A Florentine army assisted by Guelphs of other towns was met by a Siennese army reinforced by Florentine exiles, and by the cavalry of Manfred of Sicily (*q.v.*), with the result that the Florentines were totally routed at Montaperti on Sept. 4, 1260. Count Giordano, acting for Manfred, entered Florence, appointed Count Guido Novello *podestà*, and began a series of persecutions against the Guelphs. The Ghibellines even proposed to raze the walls of the city. Their triumph, however, was short-lived: Charles I. of Anjou (*q.v.*), descended into Italy as the champion of the papacy; Manfred was defeated and killed (1266), and Guido Novello and the Ghibellines were expelled and their property confiscated. But it was not the *popolo* who triumphed; the pope and Charles were the real masters of the situation. Nevertheless much of the old order was restored; the *podestà* who represented King Charles was assisted by 12 *buoni uomini*, and by the council of the 100 *buoni uomini del popolo*, but the constitution of the republic, although of very democratic tendencies, seemed designed to promote civil strife and weaken the central power.

While the constitution was evolving in a manner which seemed to argue small political ability and no stability in the Florentines, the people had built up a wonderful commercial organization. Each of the seven *arti maggiori* or greater guilds was organized like a small State with its councils, statutes, assemblies, magistrates, etc., and in times of trouble constituted a citizen militia. Florentine cloth especially was known and sold all over Europe, and the Florentines were regarded as the first merchants of the age. In 1279 Pope Nicholas sent his nephew, Cardinal Latino Frangipani Malabranca, to reconcile the parties in Florence once more. He succeeded to some extent, and was granted a kind of temporary dictatorship. He raised the 12 *buoni uomini* to 14 (eight Guelphs and six Ghibellines), to be changed every two months; and they were assisted by a council of 100. A force of 1,000 men was placed at the disposal of the *podestà* and *capitano* (now both elected by the people) to keep order and oblige the Guelph nobles to respect the law. After 1282 the signory was composed of the three (afterwards six) *priori* of the guilds, who ended by ousting the *buoni uomini*, while a *defensor artificum et artium* replaced the *capitano*; thus the republic became an essentially trading community, governed by the *popolani grassi*

or rich merchants.

The republic now turned to the task of breaking the power of the Ghibelline cities of Pisa and Arezzo. In 1289 the Aretini were completely defeated by the Florentines at Campaldino, a battle made famous by Dante's presence. Peace was made in 1293.

The Ordinamenti Della Giustizia.—The nobles, who had largely contributed to the victory, especially men like Corso Donati and Vieri de' Cerchi, were becoming more powerful, but new laws were passed to reduce their influence. These were reinforced by the *Ordinamenti della Giustizia* of 1293, by which all who were not of the *arti* were definitely excluded from the signory. The leading spirit of this reform was Giano della Bella, a noble who by engaging in trade had become a *popolano*; the nobles strenuously opposed the new measures, and in 1295 a signory favourable to them enacted a law attenuating the *Ordinamenti*.

Charles of Valois and Henry of Luxembourg.—The nobles, however, had split into two factions, the *Neri* (Blacks), headed by the Donati, and the *Bianchi* (Whites) led by the Cerchi. The pope's attempt to unite them having failed, he summoned Charles of Valois to come to his assistance, promising him the imperial crown, and in 1301 Charles entered Italy with instructions from the pope to crush the Bianchi and the *popolo* and exalt the *Neri*. On Nov. 1 Charles reached Florence. He promised to respect the laws, but the new *podestà*, Cante dei Gabrielli of Gubbio, who had accompanied Charles, punished many of the Bianchi; among those whom he exiled was the poet Dante (1302). Corso Donati, who for some time was the most powerful man in Florence, made himself many enemies by his arrogance, and the irritation against him resulted in a rising in which he was killed (1308). In the same year Henry of Luxembourg was elected king of the Romans, and with the pope's favour he came to Italy in 1310; the Florentine exiles and all the Ghibellines of Italy regarded him as a saviour and regenerator of the country, while the Guelphs of Florence regarded both him and the pope as dangerous to their liberties. In 1312 Henry was crowned emperor as Henry VII. in Rome, but circumstances made him merely a German kaiser who tried to subjugate free Italian communes. He besieged Florence without success, and died in 1313.

The 14th Century.—In 1325 further constitutional reforms were enacted. The former councils were replaced by the *consiglio del popolo*, consisting of 300 *popolani* and presided over by the *capitano*, and the *consiglio del comune* of 250 members, half of them nobles and half *popolani*, presided over by the *podestà*. The *priori* and other officers were drawn by lot from among the Guelphs over 30 years old who were declared fit for public office by a special board of 98 citizens (1329).

From 1313 to 1338, the Florentines waged war with varying success against Pisa and Lucca. Finally, by the peace of 1339 they obtained a part of Lucchese territory. At the same time they purchased from the Tarlati the protectorate over Arezzo for ten years. But misfortunes fell on the city: Edward III. of England repudiated the heavy debts contracted for his wars in France with the Florentine banking houses of Bardi and Peruzzi (1339), and this eventually led to their bankruptcy, shaking Florentine credit all over the world; Philip VI. of France extorted large sums from the Florentine merchants and bankers in his dominions by accusing them of usury; in 1340 plague and famine wrought terrible havoc in Florence, and riots again broke out between the nobles and the *popolo*. To put an end to these disorders, Walter of Brienne, duke of Athens, was elected "conservator" and captain of the guard in 1342. An astute, dissolute and ambitious man, half French and half Levantine, he succeeded in getting himself acclaimed by the populace lord of Florence for life. But by his oppressive taxes, and his ferocious cruelty, he accumulated bitter hatred against his rule. On July 26, 1343, the citizens rose in arms, demanded the duke's abdication, and besieged him in the palace. Finally on Aug. 1 he had to resign his lordship.

A *balìa*, or provisional government, was appointed to institute reforms; new constitutional changes were introduced; the

Ordinamenti were maintained, but in a somewhat attenuated form, and certain nobles as a favour were declared to be of the *popolo*. Florence became a thoroughly democratic and commercial republic, but Florentine democracy was limited to the walls of the city, for no one of the *contado* nor any citizen of the subject towns enjoyed political rights, which were reserved for the inhabitants of Florence alone, and not by any means for all of them.

Florence was, in the 14th century, a city of about 100,000 inhabitants, of whom 25,000 could bear arms; there were 110 churches, 39 religious houses; the shops of the *arte della lana* numbered over 200, producing cloth worth 1,200,000 florins, and Florentine bankers and merchants were found all over the world, often occupying responsible positions in the service of foreign Governments. It was already a centre of art and letters and full of fine buildings, pictures and libraries. But since the nobles had been suppressed politically, the lowest class of adventurer had come into prominence, thus paving the way for tyranny.

In 1347 the city was again stricken with famine, and in 1348 by a terrible plague, which carried off three-fifths of the population (according to Villani). Yet in spite of these disasters the republic was not vanquished; it soon regained the suzerainty over many cities which had broken off all connection with it and purchased the over-lordship of Prato. Giovanni Visconti, lord and archbishop of Milan, having purchased Bologna and allied himself with sundry Ghibelline houses of Tuscany with a view to dominating Florence, the city made war on him in 1351, and placed itself under the protection of the emperor Charles IV. (1355). This enabled the nobles who dominated the *Parte Guelfa* to enact stringent measures, punishing with death or heavy fines all who, being Ghibellines, held office, and to exercise a veritable reign of terror. Italy at this time began to be overrun by bands of soldiers of fortune. The first of these bands with whom Florence came into contact was the Great Company, commanded by the count of Lando, which twice entered Tuscany but was expelled both times by the Florentine troops (1358–59). From 1362–64 Florence was again at war with Pisa and the latter called Sir John Hawkwood's English company to their aid. Peace was finally made with no advantage gained on either side.

The Parte Guelfa.—The tyranny of the *Parte Guelfa* continued unabated, and the *capitani* carried an enactment by which no measure affecting the *Parte* should be even discussed by the signory unless previously approved by them. This law, however, aroused so much opposition that some of the very men who had proposed it assembled in secret to discuss its abolition, and a quarrel between the Albizzi and the Ricci having weakened the *parte*, a *balìa* of 56 was agreed upon. Several of the Albizzi and the Ricci were excluded from office for five years, and a council called the Ten of Liberty was created to defend the laws and protect the weak against the strong.

In 1375 Florence became involved in a war which showed how the old party divisions of Italy had been obliterated. The papal legate at Bologna, Cardinal Guillaume de Noëlle (d. 1394), although the Church was then allied to Florence, was meditating the annexation of the city to the Holy See; he refused a request of the Florentines for grain from Romagna, and authorized Hawkwood to devastate their territory. An alliance with Bernabò Visconti was thereupon concluded, war declared, and a *balìa* of eight, the *Otto della guerra* (afterwards called the "Eight Saints" on account of their good management) was created to carry on the campaign. Pope Gregory XI. placed Florence under an interdict, but by 1378 peace was made, partly through the mediation of St. Catherine of Siena, and the interdict was removed in consideration of the republic's paying a fine of 200,000 florins to the pope.

During the war the eight had been practically rulers of the city, but now the *Parte Guelfa*, led by Lapo da Castiglionchio and Piero degli Albizzi, attempted to reassert itself. Salvestro de' Medici, however, who had always opposed the *parte*, was elected *gonfaloniere* in spite of its intrigues (1378), and the people were anxious to break the power of the *parte* for good. A large body of wool carders gathered outside the city and conspired to sub-

vert the signory and establish a popular Government. Although the plot, in which Salvestro does not seem to have played a part, was discovered, a good deal of mob violence occurred, and on July 21 the populace seized the podestà's palace, which they made their headquarters. Once the people were in possession of the palace, a carder named Michele di Lando took the lead. Master of Florence for one day, he quelled disorder and pillage, and reformed the Constitution. But to satisfy the people several of the nobles, including Piero degli Albizzi, were put to death on charges of conspiracy, and many others were exiled. Perpetual rioting and anarchy succeeded, until at last, in 1382, a reaction set in, and order was restored by the guild companies. Again a new constitution was decreed by which the *gonfaloniere* and half the *priori* were to be chosen from the greater guilds and the other half from the lesser. The demagogues were executed or forced to fly, Michele di Lando was exiled, and the Guelph families gradually regained much of their lost power.

Pisa.—In 1393 Maso degli Albizzi was made *gonfaloniere*, and for many years remained almost master of Florence. A severe persecution was initiated against the Alberti and other families, who were disfranchised and exiled. Disorders and conspiracies against the merchant oligarchy continued, and the exiles caused the republic much trouble by intriguing against it in foreign States. In 1397–98 Florence was at war with Gian Galeazzo Visconti, who, aspiring to the conquest of Tuscany, acquired the lordship of Pisa, Siena and Perugia; but just as the Milanese were about to march on Florence, Visconti died. His territories were divided between his sons and his *condottieri*. In 1404 the Florentines' attempt to capture Pisa single-handed failed, and Gabriele Maria Visconti, lord of Pisa, placed himself under the protection of the French king. The Florentines then made overtures to France, who had supported the anti-popes all through the Great Schism, and suggested that they too would support the then anti-pope, Benedict XIII., in exchange for the sale of Pisa. With French support they purchased the city in 1405, but a few days later the citizens rose in arms and recaptured it from the mercenaries. There was great consternation in Florence at the news, and the Florentines attacked Pisa once more. After a six months' siege it surrendered on terms (Oct. 9, 1406), and Florence acquired a great seaport and was at last able to develop a direct maritime trade.

Except in connection with the Pisan question, the republic had taken no definite side in the Great Schism which had divided the Church since 1378, but in 1408 she appealed both to Pope Gregory XII. and the anti-pope, Benedict XIII., and suggested a council within her own territory. Gregory refused, but after consulting a committee of theologians who declared him to be a heretic, the council promoted by Cardinal Cossa and other independent prelates met at Pisa. The council deposed both popes and elected Pietro Filargi as Alexander V. (June 26). But Ladislas of Naples still occupied the papal States, and Florence, alarmed at his growing power and ambition, formed a league with Siena, Bologna and Louis of Anjou who laid claim to the Neapolitan throne, to drive Ladislas from Rome. Cortona, Orvieto, Viterbo and other cities were recovered for Alexander, and in Jan. 1410 Rome itself was captured by the Florentines under Malatesta dei Malatesti. Alexander having died in May, Cardinal Cossa was elected as John XXIII., and Florence purchased Cortona from the pope.

ASCENDENCY OF THE DE' MEDICI

Giovanni de' Medici.—In 1421 Giovanni de' Medici was elected *gonfaloniere* of justice, an event which marks the beginning of that family's power. The same year the republic purchased Leghorn from the Genoese for 100,000 florins, and established a body of "Consuls of the Sea" to superintend maritime trade. Filippo Maria Visconti, who had succeeded in reconquering most of Lombardy, seized Forlì. The Florentines declared war on him, and through Venetian intervention, Visconti was finally defeated and forced to accept peace on onerous terms (1427).

The old systems of raising revenue no longer corresponded to the needs of the republic, and as early as 1336 the various loans

made to the State were consolidated into one national debt (*monte*). Subsequently all extraordinary expenditure was met by forced loans (*prestanze*), but owing to the general discontent a *catasto* or assessment of all the wealth of the citizens was made in 1427, and measures were devised to distribute the obligations according to each man's capacity, so as to avoid pressing too hardly on the poor. The *catasto* was largely the work of Giovanni de' Medici, who greatly increased his popularity thereby. He died in 1429.

Cosimo de' Medici.—An attempt to capture Lucca led Florence, in alliance with Venice, into another costly war with Milan (1432–33). The mismanagement of the campaign brought about a quarrel between the aristocratic party, led by Rinaldo degli Albizzi, and the popular party led by Giovanni de' Medici's son Cosimo (1389–1464). Rinaldo succeeded in getting Cosimo exiled, but his proposal for a *coup d'état* met with no response from his own party, and he failed to prevent the election of a pro-Medici signory in 1434. A revolution was only averted through the intervention of Pope Eugene IV. A *parlamento* was summoned, and the *balìa* appointed decreed the return of Cosimo and the exile of Rinaldo degli Albizzi and others. On Oct. 6, 1434, Cosimo returned to Florence, and for the next three centuries the history of the city is identified with that of the house of Medici.

Cosimo succeeded in dominating the republic while remaining nominally a private citizen. He exiled those who opposed him, and governed by means of the *Balìa*, which, re-elected every five years, appointed all the magistrates and acted according to his orders. In 1437 Florence and Venice were again at war with the Visconti, whose chief captain, Niccolò Piccinino (*q.v.*), on entering Tuscany with many Florentine exiles in his train, was signally defeated at Anghiari by the Florentines under Francesco Sforza (1440); peace was made the following year. The system of the *catasto*, which led to abuses, was abolished, and a progressive income tax (*decima scalata*) was introduced with the object of lightening the burdens of the poor, who were as a rule Medicean, at the expense of the rich.

Lorenzo the Magnificent.—In 1464 Cosimo died and was succeeded, not without some opposition, by his son, Piero, who was very infirm. Various plots against him were hatched, but Piero's unexpected energy upset the schemes of his enemies. He died in 1469, leaving two sons, Lorenzo (1449–92) and Giuliano (1453–78). The former at once assumed the reins of government and established his domination by means of Provisional Governments consisting entirely of Mediceans, to be renewed every five years (1471). In 1472 a quarrel having arisen with Volterra, Lorenzo sent an expedition against the city, which was sacked, and many of the inhabitants massacred. Owing to a variety of causes an enmity arose between Lorenzo and Pope Sixtus IV., and the latter, if not an accomplice, at all events had cognizance of the Pazzi conspiracy against the Medici (1478). The result of the plot was that Lorenzo strengthened his position, and put to death or exiled numbers of his enemies. He was excommunicated by Sixtus, who, together with King Ferdinand of Naples, waged war against him. Eventually the Florentines were defeated at Poggio Imperiale and the city itself was in danger. Lorenzo by his boldness in going to Naples succeeded in concluding a peace with the king, which led to a reconciliation with the pope (1479–80). He was received with enthusiasm on returning to Florence and became absolute master of the city. From that time until his death the city was free from party strife under a *de facto* despotism. Owing to his political activity Lorenzo had neglected the business interests of his firm, and in order to make good certain heavy losses he seems to have appropriated public funds. His foreign policy, which was magnificent but expensive, rendered further forced loans necessary.

An attempt by the Venetians to seize Ferrara led to a general Italian war, in which Florence also took part on the side hostile to Venice, and when peace was made in 1484, the republic gained some advantages. The following year a revolt of the Neapolitan barons against King Ferdinand broke out, actively supported by Pope Innocent VIII.; Lorenzo remained neutral at first, but he ended by giving Ferdinand assistance in spite of the king's un-

popularity in Florence. Peace was made in 1486, and in 1487 Lorenzo regained Sarzana, which Genoa had taken from Florence nine years previously. The general disorders and ceaseless intrigues all over Italy required Lorenzo's constant attention, and he succeeded in making Florence "the needle of the balance of power in Italy." At this time the Dominican friar, Girolamo Savonarola (*q.v.*), was in Florence, and aroused the whole city by his denunciations of ecclesiastical corruption and also of that of the Florentines. He opposed Lorenzo's Government as the source of the immorality of the people, and to some extent influenced public opinion against him. Ill-health now gained on Lorenzo, and Savonarola, whom he had summoned to his bedside, refused to give absolution to the destroyer of Florentine liberties. Lorenzo died in 1492.

Expulsion of the Medici, 1494.—He was succeeded by his son Piero, who had none of his father's capacity and made many blunders. When Charles VIII. of France came to Italy to conquer Naples, Piero decided to assist the latter, but as soon as Charles had entered Florentine territory and captured Sarzana, Piero went to his camp and asked pardon for opposing him. The king demanded the cession of Pisa, Leghorn and other towns, which Piero granted, but on returning to Florence on Nov. 8, 1494, he was refused admittance to the palace, and the people began to shout "Popolo e libertà!" in opposition to the Medicean cry of "Palle, Palle!" (from the Medici arms). With a small escort he fled from the city, followed soon after by his brother Giovanni. That same day Pisa rose in revolt against the Florentines, and was occupied by Charles. The expulsion of the Medici produced some disorder, but Piero Capponi (*q.v.*) and other prominent citizens succeeded in keeping the peace. Charles entered Florence on Nov. 17 at the head of 12,000 men. He was impressed with the wealth and refinement of the citizens, and above all with the solid fortress-like appearance of their palaces. But his demands by no means pleased the Florentines, and when the king began to hint at the recall of Piero de' Medici, whose envoys had gained his ear, the signory ordered the citizens to be ready to resort to arms. The proposal was dropped, but Charles demanded an immense sum of money before he would leave the city. The syndics refused to accept his insolent ultimatum, and the king said in a threatening tone, "Then we shall sound our trumpets," whereupon Capponi tore up the document in his face and replied, "And we shall ring our bells." The king, realizing what street fighting in Florence would mean, at once came to terms; he contented himself with 120,000 florins, agreeing to give up the fortresses he had taken and to keep the Medici in exile. But it was not until Nov. 28, after an exhortation by Savonarola, whom he greatly respected, that he left Florence.

Savonarola.—It was intended to re-establish the Government on the basis of the old republican institutions, but it was found that 60 years of Medici rule had reduced them to mere shadows, and the condition of the Government was utterly chaotic. Consequently men talked of nothing save of changing the Constitution, but, unfortunately, there was no longer an upper class accustomed to public affairs, while the lower class was thoroughly demoralized. Savonarola, who had already made a reputation as a moral reformer, began his famous series of political sermons, and gradually a new Government was evolved, each law being enacted as the result of his exhortations. A Greater Council empowered to appoint magistrates and pass laws was formed, to which all citizens who had paid their taxes, and *beneficiati* (*i.e.*, who had sat in one of the higher magistracies, or whose fathers, grandfathers or great-grandfathers had done so) were eligible. There were 3,200 such citizens, and they sat one-third at a time for six months. The Greater Council was to elect another council of 80 citizens over 40 years old; this body was to appoint ambassadors and commissaries of war, and deal with other confidential matters. The system of forced loans was abolished and a 10% tax on real property introduced in its stead, and a law of amnesty for political offenders enacted. Savonarola also proposed a court of appeal for criminal and political offences tried by the *Otto di guardia e balla*; this too was agreed to, but the right of appeal was to be, not to a court, as Savonarola suggested, but to

the Greater Council, a fact which led to grave abuses, as judicial appeals became subject to party passions. But in spite of Savonarola's popularity, there was a party called the *Bigi* (greys) who intrigued secretly in favour of the return of the Medici, while the men of wealth, called the *Arrabbiati*, although they hated the Medici, were even more openly opposed to the actual regime. The adherents of Savonarola were called the *Piagnoni*, or snivelers, while the *Neutrali* changed sides frequently.

A league between the pope, the emperor, Venice and Spain having been made against Charles VIII., the French king was forced to return to France. On his return journey he violated his promise by giving aid to the Pisans in their revolt against Florence, and did not restore the other fortresses. Piero de' Medici's attempt to seize Florence failed, but the conditions of the city were not prosperous; its resources were strained by the sums paid to Charles and by the war, its credit was shaken, its trade paralysed; famine and plague visited the city, and the war to subjugate Pisa was proceeding unsatisfactorily. Worse still was the death, in 1496, of one of its ablest and most disinterested statesmen, Piero Capponi. The league now attacked Florence, for Pope Alexander VI. hated Savonarola and was determined to destroy the republic, so as to reinstate the Medici temporarily, and prepare the way for his own sons; the Venetians and Imperialists besieged Leghorn, and there was great misery in Florence. All this decreased Savonarola's popularity to some extent, but the enemy having been beaten at Leghorn and the league being apparently on the point of breaking up, the Florentines took courage and the friar's party was once more in the ascendant. Numerous processions were held, Savonarola's sermons against corruption and vice seemed to have temporarily transformed the citizens, and the carnival of 1497 remained famous for the burning of the "vanities" (*i.e.*, indecent books and pictures and carnival masks and costumes). The friar's sermons against ecclesiastical corruption, and especially against the pope, resulted in Savonarola's excommunication. The party hostile to him gained ground with the support of the Franciscans, who disliked the Dominican order. The pope again and again demanded that the friar be surrendered to him, but, in spite of his threats of an interdict against the city, without success. In 1498, however, a signory of *Arrabbiati* having been elected, Savonarola was arrested and imprisoned. The commission appointed to try him on charges of heresy and treason was composed of his enemies; many irregularities were committed during the three trials, and the prisoner was repeatedly tortured. The outgoing signory secured the election of another which was of their way of thinking, and on May 22, 1498, Savonarola was condemned to death and executed the following day.

Piero Soderini.—The pope having been satisfied, the situation in Florence was less critical for the moment. But Cesare Borgia suddenly demanded the reinstatement of the Medici in Florence, and the danger was only warded off by appointing him captain-general of the Florentine forces at a large salary (1501). The weakness of the Government became every day more apparent. In 1502, in order to give more stability to the Government, the office of *gonfaloniere*, with the right of proposing laws to the signory, was made a life appointment. The election fell on Piero Soderini (1448–1522), an honest public-spirited man of no particular party, but lacking in strength of character. One useful measure which he took was the institution of a national militia, at the suggestion of Niccolò Machiavelli (1505). In the meanwhile the Pisan war dragged on until in 1509 the city was driven by famine to surrender and became a dependency of Florence once more.

The Schismatic Council of Pisa.—In 1510 Pope Julius II., having seceded from the league of Cambrai, in which he had joined France and Spain against Venice, raised the cry of "Fuori i Barbari" (out with the barbarians), with a view to expelling the French from Italy. King Louis thereupon proposed an oecumenical council and demanded that it be held in Florentine territory. The republic agreed to the demand, and the council was opened at Pisa, whereupon the pope immediately placed Florence under an interdict. A Spanish army under Raymundo de Cardona

entered the republic's territory and demanded 100,000 florins, the dismissal of Soderini, and the readmission of the Medici. Soderini offered to resign, but the Greater Council supported him and preparations for defence were made. In August the Spaniards took Prato by storm and committed hideous atrocities on the inhabitants; Florence was in a panic, a group of the nobles forced Soderini to resign and leave the city, and Cardona's new terms were accepted, viz., the readmission of the Medici, a fine of 150,000 florins and an alliance with Spain.

Return of the Medici, 1512.—On Sept. 1, 1512, Giuliano and Giovanni de' Medici, and their nephew, Lorenzo, entered Florence with the Spanish troops, and a constitution similar to that of Lorenzo the Magnificent was created. Giuliano became *de facto* head of the Government, but he did not pursue the usual vindictive policy of his house. In 1513, on the death of Julius II., Giovanni de' Medici was elected pope as Leo X. In March 1514 Giuliano died, and was succeeded by Lorenzo, who was also created duke of Urbino. At his death, in 1519, Cardinal Giulio de' Medici took charge of the Government. He did not rule badly and maintained at all events the outward forms of freedom. In 1523 he was elected pope, as Clement VII., and sent his relatives, Ippolito and Alessandro, both minors and bastards, to Florence under the tutorship of Cardinal Silvio Passerini.

Second Expulsion of the Medici, 1527.—Cardinal Passerini's regency proved most unpopular, and the city was soon seething with discontent. Revolts broke out and Passerini showed himself quite unequal to the situation. The nobles were mostly anti-Medicean, and when Filippo Strozzi, and above all his wife, threw their influence in the scales against the Medici, and the magistrates declared for their expulsion from power, Passerini, Ippolito and Alessandro left Florence (May 17, 1527). A *Consiglio degli Scelti* was summoned and a constitution similar to that of Savonarola's time was established. The Greater Council was revived and Niccolò Capponi created *gonfaloniere* for a year. But Florence was torn by factions. Having been re-elected *gonfaloniere* in spite of much opposition in 1528, Capponi tried to make peace with the pope, but his correspondence with the Vatican resulted in a quite unjustified charge of high treason, and although acquitted he had to resign office and leave the city for six months. Francesco Carducci was elected *gonfaloniere* in his place, and on June 29, 1529, the pope and the emperor concluded a treaty by which the latter agreed to re-establish the Medici in Florence.

Siege of Florence and Restoration of the Medici.—Carducci made preparations for a siege, but the majority of the people were against him, either from Medicean sympathies or fear, although the *Frateschi*, as the believers in Savonarola's views were called, supported him strongly. A body called the *Nove della Milizia*, of whom Michelangelo (*q.v.*) Buonarroti was a member, was charged with the defence of the city, and Michelangelo himself superintended the strengthening of the fortifications. A most unfortunate choice for the chief command of the army was the appointment of Malatesta Baglioni. In August an imperial army under Philibert, prince of Orange, advanced on the city. In September Malatesta surrendered Perugia, and other cities fell before the Imperialists. All attempts to come to terms with the pope were unsuccessful, and by October the siege had begun. Although alone against papacy and empire, the citizens showed the greatest spirit and devotion, and were successful in many sorties. The finest figure produced by these events was Francesco Ferruccio (*q.v.*); by his defence of Empoli he showed himself a first-class soldier, and was appointed commissioner-general. But Malatesta was a traitor at heart and hindered the defence of the city. Ferruccio, who had recaptured Volterra, marched to Gavinana above Pistoia, to attack the Imperialists in the rear; but in spite of his heroism he was defeated and killed (Aug. 3); the prince of Orange also fell in that desperate engagement. The signory, at last realizing that Malatesta was a traitor, dismissed him; but it was too late, and he now behaved as though he were governor of Florence; when the troops attempted to enforce the dismissal he turned his guns on them. On Aug. 9 the signory saw that all hope was lost and entered into negotiations with Don Ferrante Gonzaga, the new imperial commander. On the 12th the capitulation was

signed; Florence was to pay an indemnity of 80,000 florins, the Medici were to be recalled, the emperor was to establish the new Government, "it being understood that liberty is to be preserved." Baccio Valori, a Medicean who had been in the imperialist camp, took charge, and the city was occupied by foreign troops. A *parlamento* was summoned, the usual packed *balia* created, and all opposition silenced. The city was given over to Pope Clement, who, disregarding the terms of the capitulation, had Carducci and Girolami (the last *gonfaloniere*) hanged, and established Alessandro de' Medici, the natural son of Lorenzo, duke of Urbino, as head of the republic on July 5, 1531. The next year the signory was abolished, Alessandro created *gonfaloniere* for life, and his lordship made hereditary in his family by imperial patent. Thus Florence lost her liberty, and came to be the capital of the duchy (afterwards grand-duchy) of Tuscany.

The 19th Century.—The Medici dynasty ruled in Tuscany until the death of Giall Gastone in 1737, when the grand-duchy was assigned to Francis, duke of Lorraine. In 1809 Florence was made capital of the Napoleonic kingdom of Etruria, but after the fall of Napoleon in 1814, the grand duke Ferdinand III. was reinstated. He died in 1833, and was succeeded by Leopold II. In 1848 there was a liberal revolutionary movement in Florence and Leopold granted a constitution. But civil disorders followed, and in 1849 the grand-duke returned under an Austrian escort. In 1859, after the Franco-Italian victories over the Austrians in Lombardy, Leopold was expelled and Tuscany annexed to the Sardinian (afterwards Italian) kingdom.

In 1865 Florence became the capital of the kingdom of Italy, but after the occupation of Rome in 1870 during the Franco-Prussian War, the capital was transferred to the Eternal City (1871). (For the history of Florence, 1434–1737, see especially MEDICI. For the period 1530–1860, see TUSCANY.)

BIBLIOGRAPHY.—The best complete history of Florence is Gino Capponi's *Storia della Repubblica di Firenze* (2 vols., Florence, 1875), a standard work based on original authorities; see also F. T. Perrens, *Histoire de Florence* (9 vols., 1877–90). For the early period see Pasquale Villari, *I. Primi Due Secoli della storia di Firenze* (Eng. ed., 1894); R. Davidsohn, *Geschichte der Stadt Florenz* (1896, etc.); P. Villari, *Machiavelli* (Eng. ed., 1892), and *Savonarola* (Eng. ed., 1896). For English histories of Florence see H. E. Napier, *Florentine History* (6 vols., 1846–47); T. A. Trollope, *History of the Commonwealth of Florence* (4 vols., 1865). See also the bibliographies of MEDICI, MACHIAVELLI, SAVONAROLA, TUSCANY, etc. (P. V.; L. V.)

FLORENCE, a city of north-western Alabama, U.S.A., on the north bank of the Tennessee river, in the Muscle Shoals district; the county seat of Lauderdale county. It is on the Lee and the Jackson highways and is served by the Louisville and Nashville and the Southern railways, and by river steamers. The population was 10,529 in 1920 (22% negroes) and was 11,729 in 1930 by the Federal census. Florence is in the fertile river valley, at the edge of the coal and iron region of the State. Just above it is the great Wilson dam, and across the river are the Government nitrate plants. The city has a number of manufacturing industries. It is the seat of a State normal school, established in 1872, the oldest normal school in the entire South. Florence was founded in 1818, and for several years was a commercial rival of Nashville. Among the early property holders were Andrew Jackson and James Madison. During the Civil War the town was raided several times (on Feb. 8, April 11, May 26, and Dec. 11, 1863), by the Federal forces. The city was chartered in 1889. It has a commission form of government.

FLORENCE, a city of Fremont county, Colorado, U.S.A., on the Arkansas river, 33m. W.N.W. of Pueblo, at an altitude of 5,187 feet. It is on Federal highway 50, and on the State highway running north through Phantom Canyon and south to the San Isabel national forest; and is served by the Denver and Rio Grande Western and the Santa Fe railways. The population was 2,629 in 1920, and was 2,475 in 1930 by the Federal census. An irrigated agricultural district adjoins Florence on the east, and in the mountains to the south famous head lettuce is grown for the eastern markets. There is a large zinc smelter in the city, and two refineries which handle oil from the northern part of the State as well as from the local field. Just east of Florence are two cement plants, with an annual output of over 2,000,000

barrels. Coal mines touch the city boundaries, and the lead mined in the Greenhorn mountains is shipped from here. Florence is a centre for many excursions. The city maintains a camp for motorists in the mountains of the San Isabel forest, 22m. south. The city was settled about 1875 and incorporated in 1887.

FLORENCE, a city of north-eastern South Carolina, U.S.A., in the Pee Dee section of the coastal plain; county seat of Florence county. It is on Federal highways 17, 76 and 601; has a municipal airport (144ac.); and is served by the Atlantic Coast Line and the Seaboard Air Line railways. The population was 10,968 in 1920 (43% negro) and was 14,774 in 1930 by the Federal census. It is an important wholesale distributing centre, and has large railroad shops, lumber mills, sash and door and veneer factories and various other manufacturing industries. Hydro-electric power is available. Florence is the seat of the State industrial school for boys; of an experiment station of Clemson college, and the district offices of its extension service; and of a boll-weevil laboratory of the Federal department of agriculture. The public library has an exceptionally good collection on Carolina colonial history. There is a beautiful national cemetery here, containing 3,019 graves. The city was founded about 1856 and incorporated as a city in 1890. It has a commission form of government. Between 1900 and 1920 the population increased 136%.

FLORENTIUM, the name given to element No. 61 by L. Rolla and L. Fernandes, who claim to have deposited a paper announcing its discovery with the Accademia dei Lincei in June 1924. On the other hand, B. S. Hopkins disputes this claim (see *J. Franklin Inst.*, 1927, 204, p. 1) and has named the element "illinium," under which title it is described. (See also RARE EARTHS.)

FLORES, capital of the Guatemalan province of Peten, located about 275m. N.N.E. of Guatemala city. Population estimated at 6,000, the only town of such size in the region. Its exports are chicle (the gum of the chicle-zapote tree and the basis of chewing-gum), mahogany and Spanish cedar. Flores can be reached via Chianaja, Guatemala, and up the River Pasión from Sebol, but the ordinary route is overland from Belize, British Honduras. Flores is the distributing and exporting centre for the entire region, the chicle bales going via Belize and the hardwoods being floated down the river. The whole region, except for the clearings where foods for local consumption are raised, is a heavily wooded tropical wilderness, abounding in an immense variety of hardwoods, which are not shipped as the market is limited and many of them are too heavy to float in water. Flores is the centre of extensive archaeological expeditions into the history and ruins of the old Maya empire. The ruins of hundreds of villages and scores of immense ancient cities are buried in the forests of Peten, their discovery as reported from time to time by American and British archaeologists following expeditions into the trackless, steaming forests, the only guides to which are the "chicleros" or chicle-gatherers. Petroleum seepages have been discovered in Peten, but the cost of carrying in drilling equipment and the construction of pipe-lines should oil wells be struck, have, up to the present time, prevented the development of this resource. (W. THO.)

FLORES, an island forming part of the Azores archipelago. Pop. (1920) 6,662; area, 57 sq.m. Flores and the adjacent island of Corvo (pop. 661; area, 7 sq.m.) constitute the westernmost group of the Azores, from the rest of which they are widely severed. It derives its name from the abundance of the flowers that find shelter in its deep ravines. Its capital is Santa Cruz das Flores (3,202). In 1591 Flores was the station of the English fleet before the famous sea fight between Sir R. Grenville's ship "Revenge" and a Spanish fleet of 15 vessels. See AZORES.

FLORES, one of the Lesser Sunda islands, of the Dutch East Indies. It is the last large island of the chain which extends eastwards from Java, and lies between Celebes and Timor. Flores has an area of 8,870 sq. miles, is 224 miles in length, and 37 in width. It is attached politically to the residency of Timor, has an assistant-resident at Ende, and is subdivided into Ende, Larantuka, Maumere, Ngada, and Ruteng, each under a *controleur*. Flores is a long, narrow island, extending from east to

west, and with several deep inlets, the chief being Maumere bay, on the North coast, in the east, in which is the island of Great Bastard, or Pulo Besar. On the North coast, too, are Todo bay and Celebes bay, on the West coast, Bajo bay and Parapat bay (with Sendal island), on the South coast, Aimere bay and the Gulf of Ende, and on the East coast Okka and Konga bays, two deep inlets, the former cutting through high mountains. The island is very mountainous, and heights are reached such as Amburombo (7,050 ft.), Rokka (7,366 ft.) and Pocho Likka (7,815 ft.), in the north-west group, Mt. Egon (5,587 ft.) and Mt. Lobetobi (5,590 ft.), in the east, and Mt. Aomasi (5,289 ft.) and Mt. Bara (5,679 ft.), in the centre. The interior, which is heavily forested, has been but little explored, but the existence of slates, chalk and sandstones, with eruptive rocks, and volcanoes, indicates that geologically the island is similar in structure to others of the Lesser Sunda chain. The few rivers known run either northwards or southwards, and do not seem to be navigable, with the exception of the Reo river, for about a mile. In northern Manggarai, in the north-west, where there is a considerable area of limestone, the rivers sometimes run underground. The mean temperature ranges from 77° to 80° and the average yearly rainfall is 47.44. Little is known of the flora and fauna, but the former includes, in the forests, coconut palms, and the sapan, cinnamon and sandal tree. The population of Flores in 1920 was 433,038; it is mainly of a mixed Malay-Papuan type. In the west, the Manggarese have more of the Malayan characteristics, whilst in the central and eastern parts the people are more Papuan in appearance. In addition to these there are settlers all round the coast from Macassar, Sumba, Sumbawa and the Solor isles; in Todo, Manggarai, are colonists said to be descended from Menangkabau Malays; and on the Ende coast are descendants of ship-wrecked Chinese. The indigenous population is largely heathen, but there are many Christians amongst the people of the east coast, and there are a number of Mohammedans in Manggarai. The people of Ende and Manggarai are the most developed, those of Central Flores the most savage and warlike, but industry everywhere is at a low stage of development, and the people get their living mostly by fishing, hunting and agriculture. Maize is the chief food, though rice is also grown, and coconuts are cultivated, copra forming the chief article of export. Other items are coffee, sandal wood, cinnamon, tobacco, mother-of-pearl and trepang. Coffee is grown in the districts of Manggarai and Ngada, in the west, and tobacco, in the highlands, whilst cotton is cultivated under Dutch supervision. Iron, brimstone, pumice-stone and saltpetre are found. Horses, buffaloes, pigs, dogs and fowls are kept, but meat is little eaten, except at festivals. *Baju* and *sarong*, or even trousers, are worn generally in the east and south, and often *sarong* only in the west, ceremonial garments are very elaborate, and many ornaments are worn. The form of house varies greatly. In Ngada houses are built on terraces, often on piles, and they are neat and regular in arrangement, and are surrounded by a hedge of bamboo, in Manggarai they are conical in form, with a roof reaching to the floor, divided into separate rooms for different families, and a passage, where unmarried men and strangers sleep, in the east the houses are smaller and inhabited by one family only, whilst in Ende they are square, roomy and well-built. Each village has its barns, and generally a *pemali* house. Generally the ground is owned communally, by the tribe, and the head man, *tuan tanah*, has great power, but hereditary tenure of the individual prevails in Ngada, and here a stranger may own the uncultivated land he breaks up, whereas in the remainder of the island he has no rights. Marriage is patriarchal in character, the women having no freedom of choice. Large dowries are paid for wives, and the husband must assist, or work for, the bride's parents until the dowry is fully paid. Polygamy is rare, also divorce; child-betrothal is common. Generally the dead are buried, and if wealthy, in wooden coffins, but in central Flores, corpses are exposed on scaffoldings. Society is divided into the noble, middle and lower classes, but now that slavery has been abolished, this latter class tends to disappear. Dutch rule reaches the people through their own chiefs and is weaning them gradually from a state of savagery to one of semi-civil-

zation, which is apparent already in most of the coastal districts. Endeh, Aimere, Reo and Labuan, are ports of call for vessels of the Royal Packet Navigation Co. Flores originally was tributary to princes of Celebes, including Macassar, and when their power was broken by the Dutch in 1667, the island became open to Dutch influence, though Larantuka, in the east, together with some of the neighbouring islands, was claimed by Portugal, and in 1818 a commission confirmed Portugal's right. In this year the Dutch stationed an official at Endeh bay, to suppress piracy, but no impression was made until 1838, when the place was bombarded and seven chiefs journeyed to Kupang, in Timor, to apologize for their piratical activities. A treaty was then made with these, and other chiefs of Endeh. Trouble with the Portuguese authorities in Larantuka and the island of Solor in 1848 led to negotiations with Portugal when, in return for the remission of certain debts, the Portuguese Government renounced all claims to Larantuka and the neighbouring islands, and though the treaty embodying this was not ratified until 1859, Dutch troops were sent to garrison the ceded districts in 1851. Later the troops were withdrawn and a civil official appointed, to reside at Larantuka, and for many years afterwards there was considerable trouble here, and at Endeh, on account of slave raids and piracy. The Rajah of Larantuka, a Christian, was the principal cause of annoyance, and his arrest and banishment, in 1905, led to a peaceful state of affairs. A treaty was concluded in 1874 with one of the principal chiefs of central Flores, but attempts made in 1887, 1888 and 1889, to penetrate into the interior failed, and in 1890 two large military expeditions were compelled to withdraw, owing to the hostility of the natives. Eventually, from Endeh, as a base, a body of mounted police succeeded in penetrating and pacifying the whole of the inland region (1907), and civil government was established. Manggarai has always been associated with the Sultan of Bima, in Sumbawa, the Dutch have only once interfered—to suppress a small rising, in 1909—and it remains so now, made into two divisions in 1915, with administrative officials at Reo and Ruteng. The other States of Flores are all under the "short declaration," which allows them some measure of self-government, under Dutch supervision. (E. E. L.)

FLOREZ, ENRIQUE (1702–1773), Spanish historian, was born at Valladolid. He was responsible for collecting most of the material that appeared in the first 26 volumes of *España Sagrada, teatro geografico-historico de la Iglesia de España* (1754–1886), a vast compilation of Spanish ecclesiastical history which obtained a European reputation.

FLORIAN, SAINT, a martyr honoured in Upper Austria. In the 8th century Pucche was mentioned as the place of his tomb, and on the site was built the celebrated monastery of canons regular, St. Florian, which still exists. His *Acta*, devoid of historical value, are based on the *Acta* of St. Irenaeus of Sirmium. The cult of St. Florian was introduced into Poland in 1183 by Giles, bishop of Modena. His protection is often sought against fire and his feast kept on May 4.

FLORIAN, JEAN PIERRE CLARIS DE (1755–1794), French poet and romance writer, was born at the château of Florian, near Sauve, in the department of Gard. His uncle and guardian, the marquis of Florian, who had married a niece of Voltaire, introduced him at Ferney and in 1768 he became page at Anet in the household of the duke of Penthièvre, who remained his friend throughout his life. He then studied at the artillery school at Bapaume and became a captain of dragoons. On the outbreak of the French Revolution he retired to Sceaux, but he was soon discovered and imprisoned; and though his imprisonment was short he survived his release only a few months, dying on Sept. 13, 1794. His famous collection of *Fables* appeared in 1792. Florian imitated Salomon Gessner, the Swiss idyllist, and his style has all the artificial delicacy and sentimentality of the Gessnerian school. Among the best of his fables are reckoned "The Monkey showing the Magic Lantern," "The Blind Man and the Paralytic" and "The Monkeys and the Leopard." He also wrote plays, pastoral novels and romances.

The best edition of Florian's *Oeuvres complètes* appeared in Paris

in 16 volumes, 1820; his *Oeuvres inédites* in 4 volumes, 1824.

See "Vie de Florian," by L. F. Jauffret, prefixed to his *Oeuvres posthumes* (1802); A. J. N. de Rosny, *Vie de Florian* (Paris, An V.); Sainte-Beuve, *Causeries du lundi*, t. iii.; A. de Montvaillant, *Florian, sa vie, ses oeuvres* (1879); *Lettres de Florian à Mme de la Briche*, published, with a notice by the baron de Barante, in *Mélanges* published (1903) by the Société des bibliophiles français; G. Gaillard, *Florian, sa vie, son oeuvre* (1912).

FLORIANOPOLIS (formerly *Desterro, Nossa Senhora do Desterro* and *Santa Catharina*, and still popularly known under the last designation), a city and port of Brazil and the capital of the State of Santa Catharina, on the western or inside shore of a large island of the same name, 485 m. S.S.W. of Rio de Janeiro, in 27° 30' S., 48° 30' W. Pop. (1920) 19,574; of the municipality, including a large rural district and several villages (1920) 41,338. The harbour is formed at a favourable part of the strait which separates the island from the mainland and is nearly 2 m. wide at this point. It is approached by narrow entrances from the north and south, which are defended by small forts. The island is mountainous and wooded, and completely shelters the harbour from easterly storms. A steel bridge, 850 metres long, now spans the strait. The surroundings are highly picturesque and tropical in character, and the town is a flourishing commercial centre though lacking railway connection inland. Its public buildings include the governor's official residence, arsenal, lyceum, hospital and some old churches. The climate is warm for the latitude, but the higher elevations of the vicinity are noted for their mild climate and healthfulness. There are some German colonies farther up the coast whose products find a market here, and a number of small settlements along the mainland coast add something to the trade of the town. The more distant inland towns are partly supplied from this point, but difficult mountain roads tend to restrict the trade greatly. There is a considerable trade in market produce with Rio de Janeiro, but the exports are inconsiderable. Florianopolis was formerly one of the well known whaling stations of the south Atlantic, and is now a secondary military and naval station.

The island of Santa Catharina was originally settled by the Spanish; Cabeza de Vaca landed here in 1542 and marched hence across country to Asunción, Paraguay. The Spanish failed to establish a permanent colony, however, and the Portuguese took possession. The island was captured by a Spanish expedition under viceroy Zeballos in 1777. A boundary treaty of that same year restored it to Portugal. In 1894 Santa Catharina fell into the possession of revolutionists against the Government of President Floriano Peixoto. With the collapse of the revolution the city was occupied by the Government forces, and its name was then changed to Florianopolis in honour of the president of the republic. (G. M. McB.)

FLORIANOPOLIS SUSPENSION BRIDGE. The Florianopolis bridge, Brazil, with a main span of 1,113ft. 9in., is the largest bridge in South America and at the date of its completion the longest eye-bar suspension span in the world. It was constructed (1923–26) for the State of Santa Catharina, Brazil, to carry a highway, electric railway and water-supply to the capital city Florianopolis situated on an island off the Atlantic coast.

The structure, designed by Robinson and Steinman, consulting engineers, is the first example of a new form of suspension bridge whereby greatly increased economy and rigidity are secured simultaneously. Its distinctive feature is the utilization of the cable to replace the middle half of the top chord of the stiffening truss and the consequent change from the conventional parallel chord truss to a stiffening truss of more effective outline, namely, with maximum depth near the quarter-points of the span. These features combined yielded a structure four times as rigid as the previous conventional design, together with a saving of one-third of the steelwork. In proportion to span and loading, the Florianopolis bridge contains less steel than any other bridge.

Another departure from conventional practice was the adoption of rocker towers, which, eliminating the customary bending stresses, contributed a saving of 20% of the steelwork in the towers and permitted the main piers to be reduced to concrete cylinders 16ft. in diam. The steel towers are 225ft. high. Instead

of wire for the cables, eye-bars were adopted; these were made of the newly developed, high-tension, heat-treated carbon steel, having a yield point exceeding 75,000 lb. per sq.in. and used with a working stress of 50,000 lb. per square inch.

In the foundation work for the main piers, novel construction methods had to be devised. By excavating and concreting successive test pits, the entire foundation area of one pier was carried down 20ft. below the bottom of the coffer dam to bed rock at elevation -60. The concrete anchorages are of novel design, U-form in plan, for maximum efficiency. The island anchorage is on rock, the continent anchorage on piles. An entirely new method was developed for the erection of the eye-bar cables and the suspended stiffening trusses, using overhead trolley, thus eliminating wooden falsework and working platforms. The bridge, which was over three years in building, provides a 28ft. roadway, a meter-gauge electric railway, a 24in. water main and a 9ft. sidewalk. Its over-all length is 2,690ft.; it contains 4,400 tons of steel and 14,500cu.yd. of concrete; and the dead weight of the main span is 4,370 lb. per linear foot.

A detailed description of the design and construction is given in a paper by D. B. Steinman and Wm. G. Grove in the *Transactions* of the Am. Soc. C.E., 1928. (D. B. S.)

FLORIDA, called the "Peninsula State" because of its peculiar outline, is the most southern State of the United States and is situated between 24° 30' and 31° N., and 79° 48' and 87° 38' W. It is bounded on the north by Alabama and Georgia, on the east by the Atlantic ocean, on the south by the Strait of Florida, which separates it from Cuba, and by the Gulf of Mexico, and on the west by the Gulf and Alabama. The Florida Keys, a chain of islands extending in a general south-westerly direction from Biscayne bay, are included in the State boundaries. The coast line is greater than that of any other State, extending 472m.

MAP OF THE MAIN ROADS OF FLORIDA

on the Atlantic and 674m. on the Gulf coast. The total area of the State is 58,666sq.m., of which 3,805sq.m. are water surface.

Physical Features.—The average elevation of the surface of the State above the sea level is less than that of any other State except Louisiana, but there is not the monotony of unbroken level which descriptions and maps often suggest. The north-western portion of the State is, topographically, similar to south-eastern Alabama, being a rolling hilly country; the eastern section is a part of the Atlantic coastal plain; the western coast line is less regular than the eastern, being indented by a number of bays and harbours, the largest of which are Charlotte harbour, Tampa

bay and Pensacola bay. Along much of the western coast and along nearly the whole of the eastern coast extends a line of sand reefs and narrow islands, enclosing shallow and narrow bodies of water—such as Indian river and Lake Worth—called rivers, lakes, lagoons, bays and harbours. In the central part of the State there is a ridge extending north and south and forming a divide, separating the streams of the east coast from those of the west. Its highest elevation above sea level is about 300 feet. The central region is remarkable for its large number of lakes, about 30,000 between Gainesville (in Alachua county) and Lake Okeechobee. They are due largely to sink holes or depressions caused by solution of the limestones of the region. Many of the lakes are connected by subterranean channels, and a change in the surface of one lake is often accompanied by a change in the surface of another. By far the largest of these lakes, nearly all of them shallow, is Lake Okeechobee, a body of water about 1,250sq.m. in area and almost uniformly shallow, its depth seldom being greater than 15 feet. Caloosahatchee river, flowing into the Gulf of Mexico near Charlotte harbour, is its principal outlet. Among the other lakes are Orange, Crescent, George, Weir, Harris, Eustis, Apopka, Tohopekaliga, Kissimmee and Istokpoga. The chief feature of the southern portion of the State is the Everglades (*q.v.*), an extremely level expanse of country, about 2,860,000ac. in area, where the natural drainage is so poor that water stands on the surface the greater portion of the year. Within the State there are many swamps, the largest of which are the Big Cypress swamp in the south, adjoining the Everglades on the west, and Okefenokee swamp, extending from Georgia into the north-eastern part of the State.

A peculiar feature of the drainage of the State is the large number of subterranean streams and of springs, always found to a greater or less extent in limestone regions. Some of them are of great size. Many of the springs have curative properties; one of them, the Green Cove spring in Clay county, discharging about 3,000gal. of sulphuretted water per minute. Not far from St. Augustine a spring bursts through the sea itself with such force that the ocean breakers roll back from it as from a sunken reef. The springs often merge into lakes, and lake systems are usually the sources of the rivers, Lake George being the principal source of the St. Johns, and Lake Kissimmee of the Kissimmee, while a number of smaller lakes are the source of the Oklawaha, one of the most beautiful of the Floridian rivers.

Government.—The present constitution was framed in 1885 and was ratified by the people in 1886. Amended from time to time it is still the fundamental law of the State. Its most important feature, when compared with the previous constitution of 1868, is its provision for the choice of State officials other than the governor (who was previously elected) by elections instead of by the governor's appointment; but the governor, who serves for four years and is not eligible for the next succeeding term, still appoints the circuit judges, who are usually nominated in primaries, and he may fill certain vacancies and may suspend, and, with the senate, remove officers not liable to impeachment. The governor is a member of the board of pardons, the other members being the attorney-general, secretary of State, controller and the commissioner of agriculture. The governor, secretary of State, attorney-general, controller, treasurer, superintendent of public instruction and commissioner of agriculture comprise a board of commissioners of State institutions; he is also a member of the Board of Education and of the Budget Commission. The office of lieutenant governor was abolished by the present constitution. The legislature meets biennially, the senators being chosen for four years, half from the odd numbered districts being elected in one election and two years thereafter half from the even numbered districts, and the representatives for two years. The senate consists of 38 members, and the house of representatives of 95, all chosen at one election; by a two-thirds vote of members present the legislature may pass a bill over the governor's veto. The judges of the supreme court and those of the 21 judicial circuits serve for six years; those of the county courts for four years, and justices of the peace (one for each justice district, of which the county commissioners must

THE LANDSCAPE IN FLORIDA

1. Marco Palms at sunset, between Marco and Caxambas, Lee County, in the Everglades, the big cypress swamp of southern Florida
2. A house of the Colonial period in Hibernia, northern Florida. The two storey porch and the curiously shaped roof of the house are frequently seen in southern buildings of this period. The large tree is live oak, with Spanish moss hanging from its branches. A palmetto is close to the porch, and date palms are in the foreground
3. Live oak (*Quercus virginiana*) covered with Spanish moss, in Hibernia. The live oak is a rugged species having small, evergreen leaves. The ubiquitous Spanish moss (*Tillandsia usneoides*) is a rootless plant, which hangs in long, grey festoons from tree-branches. It is covered with minute hairs which absorb moisture from the air
4. Ormond-Daytona Beach, a stretch of sand 30 miles long, on the Atlantic coast 68 miles south of St. Augustine. It is a famous speedway

form at least two in each county) hold office for four years. The constitutional qualifications for suffrage are: the age of 21 years, citizenship in the United States or presentation of naturalization certificates at registration centres, residence in the State one year and in the county six months, and registration. To these requirements the payment of a poll tax of one dollar has been added by legislative enactment, such an enactment having been authorized by the constitution. Insane persons and persons under guardianship are excluded by the constitution, and "all persons convicted of bribery, perjury, larceny or of infamous crime, or who shall make or become directly or indirectly interested in any bet or wager the result of which shall depend upon any election," or who shall participate as principal, second or challenger in any duel, are excluded by legislative enactment.

Amendments to the constitution may be made by a three-fifths vote of each house of the legislature, ratified by a majority vote of the people. A revision of the constitution may be made upon a two-thirds vote of all members of both houses of the legislature, if ratified by a majority vote of the people; a constitutional convention is then to be provided for by the legislature, such convention to meet within six months of the passage of the law therefor, and to consist of a number equal to the membership of the house of representatives, apportioned among the counties as are the members of that house.

A homestead of 160 ac. or of $\frac{1}{2}$ ac. in an incorporated town or city, owned by the head of a family residing in the State, with personal property to the value of \$1,000 and the improvements on the real estate, is exempt from enforced sale except for delinquent taxes, purchase money, mortgage or improvements on the property. The wife holds in her own name property acquired before or after marriage; the intermarriage of whites and negroes (or persons of negro descent to the fourth generation) is prohibited. All these are constitutional provisions.

As an administrative division of the Government, the county is very important, for it is where the chief functions of local government are carried on. Each county has a clerk of circuit court, a sheriff, constables, an assessor of taxes, a tax collector, a superintendent of public instruction and a surveyor. All of these are elected for a period of four years, except the tax assessor and the tax collector, who are elected for two years. The constitution provides for the division of each county into five districts and "one county commissioner shall be selected for each such district." The commissioners, who individually have supervision over bridges and highways and collectively exercise a general supervision over the property and finances of the county, are elected for a term of two years. The State census of 1925 showed Florida divided into 64 counties, but in 1927 this number was increased to 67.

Population.—The first United States census of Florida was taken in 1830, when the territory had a population of 34,730. The population of Florida at other selected census periods was as follows: in 1850, 87,445; in 1880, 269,493; in 1890, 391,422; in 1900, 528,542; in 1910, 752,619; in 1920, 968,470. The State census taken in 1925 showed the population in that year to be 1,263,549. The United States census figures for April 1, 1930 were 1,468,211. The increase for the decade 1910-20 was 28.7%, and for the decade 1920-30 it was even more remarkable, being 499,741, or 51.6%. In 1920, 93.3% were native born, 65.9% were white and 34% were negro. In 1930 there were 31 cities with a population of over 5,000; those then exceeding 15,000 were: Jacksonville (129,549), Miami (110,637), Tampa (101,161), St. Petersburg (40,425), Pensacola (31,579), Orlando (27,330), West Palm Beach (26,610), Lakeland (18,554), Daytona Beach (16,598). Tallahassee is the capital of the State. The rapid development of Florida cities and towns is giving the State a larger proportion of urban population than that of any other southern State. Florida's population, however, is still predominantly rural. In 1920 only 36.7% of the entire population was urban (living in places of over 2,500). During the winter months the population is largely augmented by thousands of tourists and winter residents, quite a number of whom become permanent residents or invest in Florida property. For many

years the coast resorts were the chief objectives, but many of the inland towns and cities are now attracting visitors.

Finance and Taxation.—Florida has one of the smallest bonded State debts in the Union. On June 30, 1926, it was \$601,567 at 3% per annum and was held entirely by the educational funds of the State. The treasurer's report for the fiscal year July 1, 1925, to June 30, 1926, showed the following sums: balance on

GRAPH SHOWING GROWTH OF POPULATION IN FLORIDA 1830-1925, INDICATING THE RELATIVE PROPORTIONS OF NEGRO AND WHITE AT EACH CENSUS

hand July 1, 1925, \$6,803,057; total receipts \$40,763,393; total disbursements \$29,911,133; balance on hand June 30, 1926, \$17,655,317. The chief sources of revenue were: the State road license fund (gasoline) \$7,568,858; the general revenue fund, which includes charter taxes on corporations, motor car licence fees and other taxes; the State Federal aid road fund; the State road tax fund; and the drainage bond fund. Disbursements from the principal funds were: State road licence fund \$5,732,320; general revenue fund \$4,877,185; drainage bond fund \$3,459,981; county road licence fund \$2,575,587. The total educational appropriation was \$1,669,470. The assessed values in 1925 were: real estate \$497,508,360; personal property \$83,799,242. In 1924 Florida adopted an amendment to the State constitution forbidding the legislature to levy an income or inheritance tax.

Education.—As early as 1831 an unsuccessful attempt was made to form an adequate public school fund; the first real effort to establish a common school system for the territory was made after 1835; in 1840 there were altogether 18 academies and 51 common schools, and in 1849 the legislature made an appropriation in the interest of the public instruction of white pupils, and this was supplemented by the proceeds of land granted by the United States Government for the same purpose. In 1852 Tallahassee established a public school; and in 1860, there were, according to a report of the United States Census, 2,032 pupils in the public schools of the State, and 4,486 in "academies and other schools." The Civil War, however, interrupted the early progress, and the present system of common schools dates from the constitution of 1868 and the school law of 1869. The school revenue is derived from the interest of a permanent school fund, special State and county taxes, and a poll-tax. The State constitution prescribes that "white and coloured children shall not be taught in the same school, but impartial provision shall be made for both."

The total population between the ages of five and 17, inclusive, in 1924 was 298,897, of which 266,318, or 89.1%, were enrolled in public elementary and secondary schools; an increase of 41,158 over the census of 1920. The estimated attendance of private and parochial schools was 6,796. Of the 266,318 attending the public schools, 243,218 were in kindergarten and elementary schools and 23,100 in secondary schools. The average daily attendance per year per pupil enrolled increased from 98 days in 1920 to 106.3 in 1924. During the session 1923-24, 8,312 teachers

were engaged in the public schools and the average annual salary amounted to \$698. The school expenditures in 1920 amounted to \$7,030,000; in 1924 to \$12,399,000; a per capita of population (5-17) of \$25.79 and \$41.48 respectively. Attendance is compulsory between the ages of seven and 16.

Before 1905 the State provided for higher education by the Florida State college, at Tallahassee, formerly the West Florida seminary (founded in 1857); the University of Florida, at Lake City, which was organized in 1903 by enlarging the work of the Florida Agricultural college (founded in 1884); the East Florida seminary, at Gainesville (founded 1848 at Ocala); the Normal school (for whites), at De Funiak Springs; and the South Florida Military Institute, at Bartow; but in 1905 the legislature passed the Buckman Act abolishing all these State institutions for higher education and establishing in their place the University of the State of Florida and a State Agricultural Experiment Station, both now at Gainesville, and the Florida Female college, at Tallahassee. In 1909 the legislature changed the names of the university and the college to the University of Florida and the Florida State College for Women. Both maintain the same standards for entrance and for graduation. The enrolment of the university for the session 1926-27 was 1,968; of the college for women, 1,361. Both counts are exclusive of the summer attendance. Denominational and private educational institutions of higher learning in Florida were 16 in number in 1923. Some of the more widely known of these are: John B. Stetson university (Baptist), at De Land; Rollins college (non-sectarian), at Winter Park; Southern college (Methodist Episcopal, South), at Lakeland; and Palmer college (Presbyterian) at De Funiak Springs. The coloured have facilities for advanced education in the Florida Agricultural and Mechanical college, at Tallahassee, which was organized in 1909 by enlarging the work of the State Normal school for training Negro Teachers (founded 1887). Other coloured institutions are: the Florida Baptist Academy and Cookman Institute (Methodist Episcopal, South), both at Jacksonville, and the Normal and Manual Training school (Congregational) at Orange Park. There is a school for the deaf and blind (founded 1885) at St. Augustine.

Charities and Houses of Correction.—The early history of the penal system may be characterized as one of aimless experiments followed by about 30 years of a lease system. The convicts were hired to the one highest bidder who contracted for their labour, and who, in turn, subleased the prisoners in smaller groups. He, moreover, undertook to lease all other persons convicted during the term of his contract. In 1889 the prisoners were placed under the care of a supervisor of convicts, and in 1905 the law was amended so that one or more supervisors might be appointed at the will of the governor. By 1908 there were four supervisors and one State prison physician. The present system began to take shape in 1911 when the legislature made an appropriation to establish a prison farm near Raiford. In this session also an act was passed which provided that only the physically perfect coloured males should be leased, and that all women and white males, and those not physically fit of the coloured males, should be retained at the farm. Under this arrangement about 600 coloured males were leased. Until Jan. 1, 1914, however, leaseholders of State prisoners were under contract to care for women prisoners and the infirm of both races, the State owning nothing in the way of buildings and equipment. By an act of 1921 all persons upon being admitted to the State prison were to be examined and classified into one of two classes according to physical fitness. All able-bodied males, except a number not exceeding 50 for the farm and a few for other institutions, were to make up the State convict road force. Women and the physically unfit were to be retained at the farm. The lease system for State or county prisoners is prohibited by law since Dec. 31, 1923. Corporal punishment was made unlawful by an act of the legislature in 1923. The State prison fund of three-eighths of one mill on the dollar on all property liable to assessment is to supplement the revenue of the prison farm. The general supervision of the prison farm and the convict road camps is in charge of the commissioner of agriculture and the board of commissioners of State institutions. Florida maintains an Industrial School for Boys at Mari-

anna, an Industrial School for Girls at Ocala, Florida Farm Colony (for feeble minded) at Gainesville, and an Insane Hospital at Chattahoochee. Orphanages and charitable institutions are maintained in various parts of the State by religious and benevolent organizations.

Industry, Trade and Transportation.—Florida's most extensive industry is agriculture. According to figures of the Florida Experiment Station there were approximately 5,940,000 ac. of land in farms in 1925, not including open or fenced range lands. Of this 1,400,000 ac. were in crops, and 618,000 ac. of crop lands were idle; 275,000 ac. were in fruit; 1,500,000 ac. were in pasture; and 2,147,000 ac. in woodland. On approximately one-third of the cultivated acreage crops were produced by intertillage (the growing of two or more crops on the same land at one time) and by succession planting (the growing of two or more crops in sequence on the same land in one year). The number of farms in Florida was 50,016 in 1910, 54,005 in 1920 and 59,817 in 1925. Fruit is Florida's most important crop. The citrus industry has prospered despite the fact that some of the groves in the more northern part of the State have suffered from heavy frosts in severe winters. In 1920 the production of oranges was 8,500,000 boxes, and of grape-fruit 5,000,000 boxes. In 1925 the production was 10,700,000 boxes of oranges and 6,300,000 boxes of grape-fruit. In the sub-tropical part of the State pineapples, lemons, guavas and avocados are grown profitably on a commercial scale. Other fruits produced are peaches, pears, bananas, grapes, figs and limes. The more important crops with their 1925 acreage yields and values are tabulated below.

Chief Crops of Florida in 1925

	Acres.	Production.	Value.
<i>Staple crops:</i>			\$
Corn (Maize)	580,000	8,700,000 bu.	8,700,000
Cotton	106,000	40,000 bales	3,541,000
Hay	82,000	57,000 tons	1,296,000
Sugar-cane	9,000	2,100,000 gal.	2,205,000
Sweet potatoes	29,000	2,465,000 bu.	4,060,000
Tobacco	7,000	5,460,000 lb.	1,693,000
<i>Truck crops:</i>			
Irish potatoes	23,000	2,599,000 bu.	6,757,000
Snap beans	20,530	1,663,000 hmpr.	2,494,000
Celery	4,320	2,000,000 crates	3,700,000
Cucumbers	10,830	1,256,000 hmpr.	1,520,000
Lettuce	3,400	765,000 crates	1,170,000
Peppers	3,400	1,115,000 bu.	2,787,000
Strawberries	3,170	6,023,000 qt.	1,807,000
Tomatoes	33,470	2,811,000 bu.	6,325,000
Watermelons	20,910	7,841 cars	2,352,000
<i>Fruit and nuts:</i>			
Grape-fruit	6,300,000 crates	11,340,000
Oranges	10,700,000 crates	26,750,000
Peaches	115,000 bu.	190,000
Pecans	1,340,000 lb.	348,000

There was a falling off in the production of cotton during the decade 1910-20; however, a good cotton season in 1925 and the use of short-staple cotton, which is more resistant to the boll weevil, more than doubled the State's production over the crop of 1920. The tobacco-growing section of western Florida produces profitably a shaded leaf, grown from Cuban and Sumatran seed, which is in great demand in cigar manufacturing. The pecan industry is comparatively new, most of the commercial groves having been planted since 1905. It is believed that in the northern part of the State the pecan crop may soon compete closely with the citrus crop of the southern part. The production of early vegetables for the northern markets is developing rapidly, and the Florida producer can put vegetables on the markets earlier than any of his competitors. The chief obstacles are costly transportation and inadequate railway freight and express service. Much attention was formerly paid to stock-raising, but with the taking up and development of much of what was formerly open range land, the figures for 1925 show a decided shrinkage in the production of livestock since 1920. In 1925 there were 662,000 cattle, including milch cows, valued at \$13,240,000; 61,000 sheep, valued at \$200,000; 506,000 swine, valued at \$3,289,000; 31,000

horses, valued at \$3,000,000; and 43,000 mules, valued at \$5,934,000. These livestock statistics include only farm animals.

The fisheries of Florida are valuable. In 1923 the catch was 160,162,189 lb. valued at \$5,746,148 (Bureau of Fisheries report); canned and preserved sea foods were valued at \$899,672. The total number of species of fish is about 600, and many species found on one coast are not found on the other. The kingfish and the tarpon are caught for sport, while mullet, shad, red snapper, pompano, trout, sheepshead and Spanish mackerel are of economic value. The sponge, oyster and turtle fisheries are also important.

According to the Census of Manufactures in 1927, Florida had 1,912 manufacturing establishments, which gave employment to 61,219 persons and had a total production worth \$218,790,150. In 1914 there were 2,158 establishments with a yearly output valued at \$81,112,000. The chief industry in 1923 was lumber and timber products, which engaged 22,258 persons, with an output valued at \$45,150,478. Other important industries in the order of their importance were: cigars and cigarettes; turpentine and rosin; car and general construction in steam railway repair shops; and commercial fertilizer.

In 1925 Florida produced mineral products to the value of \$10,908,000, the principal of which were phosphates, lime, limestone, brick, tile, kaolin and fuller's earth, of which last Florida produces about three-fourths of the entire U.S. output. In 1924 the production of phosphates was: land pebble, 2,348,137 long tons, valued at \$7,987,752; and hard rock, 199,516 long tons, valued at \$1,071,675. Because of exploitation, Florida's lumber production shows a decline since 1916, when an output of 1,425,000,000 board ft. was reached; the 1924 production, mainly cypress and yellow pine, was 980,014,000 board feet. Some hard wood, (chiefly hickory) is produced. Naval stores are produced from the pine forests, where the sap of the trees is collected and distilled, yielding turpentine and rosin. In 1923 Florida produced 9,747,000 gal. of turpentine, valued at \$10,000,000 and 660,000 bbl. of rosin, valued at \$4,000,000. In 1924 Florida manufactured 546,799,000 cigars, valued at \$35,000,000 and 2,767,000 cigarettes, valued at \$55,000.

An important influence in the development of Florida has been the railways and other facilities for transportation and communication. In 1880 the total railway mileage was 518, but since that date it has increased steadily; in 1900 it was 3,255, and in 1925, 5,511. The largest system is the Atlantic Coast Line, consisting of railways built or consolidated by H. B. Plant and once forming a part of the "Plant System" of railways. The railway with the next greatest mileage is the Seaboard Air Line. The Florida East Coast railway is an important system also. It was the product of one man's faith in the country, H. M. Flagler. Other important railways are: The Louisville and Nashville, the Georgia Southern and Florida, and the Charlotte Harbor and Northern. The total freight and passenger revenues for the parts of the systems operating in Florida were in 1925 \$75,000,709, according to the report of the Florida railroad commission. This commission has certain regulatory powers over all means of transportation and communication within the State. In 1925 there were 210m. of electric railways in operation, wholly as city transportation systems.

Florida's highway mileage on Dec. 31, 1926, according to U.S. Census figures, was 5,654. Of this number, 2,928m. were earth and 2,725 were surfaced. During the year 1926, 349m. of surfaced road were constructed.

In 1925, 2,328 vessels entered and 2,043 cleared from Florida ports. Of these 1,238 entered from Cuba and 1,175 cleared for that destination. The west coast ports were of chief importance in both import and export trade. For the import trade the four chief ports were: Jacksonville (with 436,930 cargo tons), Key West, Tampa and Miami; in the export trade Tampa led with 557,317 cargo tons; other ports being Key West, Pensacola and Fernandina. Within recent years much has been done by the national government, aided in some cases by the local authorities, to improve the harbours and to extend the limits of river navigation. In 1882 the Florida East Coast Line Canal and Transportation Co. was organized to develop a waterway from Jacksonville to Biscayne bay by connecting with canals the St. Johns, Ma-

tanzas and Halifax rivers, Mosquito lagoon, Indian river, Lake Worth, Hillsboro river, New river, and Snake creek; in 1908 this vast undertaking was completed, thereby opening a channel for light-draught boats. The drainage canals which connect Lake Okeechobee with the Atlantic ocean provide passage for light-draught boats between the two points.

Some index of Florida's recent business growth can be gained from the following banking statistics: deposits in national banks in Jan. 1920, \$187,286,267; in Jan. 1925, \$375,042,947; in State banks and trust companies in Jan. 1920, \$197,809,947; in Jan. 1925, \$287,636,588.

HISTORY

The romance and the tragedies of the early history of Florida give it a unique place in the annals of the American States. Within 20 years after the first voyage of Columbus to the New World in 1492, an expedition was being organized to seek for a fabulous fountain of youth and for riches in the new and inviting land. This expedition was followed by others seeking wealth or to establish the Christian faith among the savages. In turn these were followed by French Huguenots who were seeking a place of religious freedom, but the zeal of the Spaniards soon brought an unhappy end to their search. Florida also has the honour of containing the oldest European settlement within the bounds of the original United States, as St. Augustine was founded in 1565, 42 years before the English were successful at Jamestown. The Spanish Council of the Indies claimed that since 1510 fleets and ships had gone to Florida, and Florida is shown on the earliest known map of the New World, the Cantino map of 1502. In 1513 Juan Ponce de Leon (c. 1460-1521), who had been with Christopher Columbus on his second voyage, and had later been governor of Porto Rico, obtained a royal grant authorizing him to discover and settle "Bimini"—a fabulous island believed to contain a marvellous fountain or spring whose waters would restore to old men their youth or, at least, had wonderful curative powers. Soon after Easter day he came in sight of the coast of Florida, probably near the mouth of the St. Johns river. From the name of the day in the calendar, *Pascua Florida*, or from the fact that many flowers were found on the coast, the

BY COURTESY OF R. S. CAMPBELL, ST. AUGUSTINE

OLD FORT OF SAN MARCO, RENAMED FORT MARION. AT ST. AUGUSTINE Begun by the Spaniards in 1656, this fortification successfully withstood repeated English and French assaults. It was here that the Indian chief Osceola, instigator of the second Seminole war, was confined before his permanent removal to Fort Moultrie

country was named Florida. De Leon seems to have explored the coast, to some degree, on both sides of the peninsula, and to have turned homeward fully convinced that he had discovered an immense island. He returned to Spain in 1514, and obtained from the king a grant to colonize "the island of Bimini and the island of Florida," of which he was appointed *adelantado* (civil and military governor), and in 1521 he made another expedition, this one for colonization as well as for discovery. He seems to have touched at the island of Tortugas, so named on account of the large number of turtles found there, and to have landed at several

places, but many of his men succumbed to disease and he himself was wounded in an Indian attack, dying soon afterwards in Cuba. Meanwhile, in 1516, another Spaniard, Diego Miruelo, seems to have sailed for some distance along the west coast of the peninsula. The next important exploration was that of Panfilo de Narvaez. In 1527 he sailed from Cuba with about 600 men (soon reduced to less than 400); he landed early in 1528, probably at the present site of Pensacola, and for six months remained in the country, he and his men suffering terribly from exposure, hunger and fierce Indian attacks. In September, his ships being lost and his force greatly reduced in number, he hastily constructed a fleet of five boats, re-embarked, probably at Apalachee bay, and lost his life by having his boat blown out to sea while off the coast of Texas. Only four of his men, including Nuñez Cabeza de Vaca, succeeded, after eight years of Indian captivity and of long and weary wanderings, in finding their way to Spanish settlements in Mexico. Florida was also partially explored by Ferdinando de Soto (*q.v.*) in 1539-40. In the summer of 1559 another attempt at colonization was made by Tristan de Luna, who sailed from Vera Cruz, landed at Pensacola bay, and explored a part of Florida and (possibly) southern Alabama. Somewhere in that region he desired to make a permanent settlement, but he was abandoned by most of his followers and gave up his attempt in 1561.

The Huguenots.—In 1562, Jean Ribaut (1520-65), with a band of French Huguenots, landed first near St. Augustine and then at the mouth of the St. Johns river, which he called the River of May, and on behalf of France claimed the country, which he described as "the fairest, fruitfulest and pleasantest of all the world"; but he made his settlement on an island near what is now Beaufort, South Carolina. In 1564 René de Laudonnière (*d. c.* 1586), with another party of Huguenots, established Fort Caroline at the mouth of the St. Johns, but the colony did not prosper, and in 1565 Laudonnière was about to return to France when (on Aug. 28) he was reinforced by Ribaut and about 300 men from France. On the same day that Ribaut landed, a Spanish expedition arrived in the Bay of St. Augustine. It was commanded by Pedro Menéndez de Avilés (1523-74), one of whose aims was to destroy the Huguenot settlement. This he did, putting to death almost the entire garrison at Fort Caroline "not as Frenchmen but as Lutherans," on Sept. 20, 1565. The ships of Ribaut were soon afterwards wrecked near Matanzas inlet; he and most of his followers surrendered to Menéndez and were executed. Menéndez then turned his attention to the founding of a settlement which he named St. Augustine (*q.v.*); he also explored the Atlantic coast from Cape Florida to St. Helena and established forts at San Mateo (Fort Caroline), Avista, Guala and St. Helena. In 1567 he returned to Spain in the interest of his colony.

The news of the destruction of Fort Caroline and the execution of Ribaut and his followers was received with indifference at the French court; but Dominique de Gourgues (*c.* 1530-93), a friend of Ribaut but probably a Catholic, so the widely accepted story goes, organized an expedition of vengeance, not informing his men of his destination until his three ships were near the Florida coast. With the co-operation of the Indians under their chief, Saturiba, he captured Fort San Mateo in the spring of 1568 and on the spot where the garrison of Fort Caroline had been executed, he hanged his Spanish prisoners, inscribing on a tablet of pine the words: "I do this not as unto Spaniards but as to traitors, robbers and murderers." Feeling unable to attack St. Augustine, de Gourgues returned to France.

The Spanish settlements experienced many vicissitudes. The Indians were hostile and the missionary efforts among them failed. In 1586 St. Augustine was almost destroyed by Sir Francis Drake, and it also suffered severely by an attack of Captain John Davis in 1665. Not until the last decade of the 17th century did the Spanish authorities attempt to extend the settlements beyond the east coast. Then, jealous of the French explorations along the Gulf of Mexico, they turned their attention to the west coast, and in 1696 founded Pensacola. When the English colonies of the Carolinas and Georgia were founded, there was constant

friction with Florida. The Spanish were accused of inciting the Indians to make depredations on the English settlements and of interfering with English commerce, and the Spanish were in constant fear of the encroachments of the English. In 1702, when Great Britain and Spain were contending in Europe, on opposite sides, in the war of the Spanish Succession, a force from South Carolina captured St. Augustine and laid siege to the fort, but being unable to reduce it for lack of necessary artillery, burned the town and withdrew at the approach of Spanish reinforcements. In 1706 a Spanish and French expedition against Charleston, South Carolina, failed, and the Carolinians retaliated by invading middle Florida in 1708 and again in 1722. In 1740 General James Edward Oglethorpe, governor of Georgia, supported by a naval force, made an unsuccessful attack upon St. Augustine; two years later a Spanish expedition against Savannah by way of St. Simon's island failed, and in 1745 Oglethorpe again appeared before the walls of St. Augustine; but the Treaty of Aix-la-Chapelle in 1748 prevented further hostilities. Pensacola, the other centre of Spanish settlement, though captured and occupied (1719-23) by the French from Louisiana, had a more peaceful history.

The Treaty of Paris and Cession to England.—By the Treaty of Paris in 1763 Florida was ceded to England in return for Havana. The provinces of East Florida and West Florida were now formed, the boundaries of West Florida being 31° N. lat. (when civil government was organized in 1767, the northern line was made 32° 28'), the Chattahoochee, and the Apalachicola rivers, the Gulf of Mexico, Mississippi sound, Lakes Borgne, Pontchartrain and Maurepas, and the Mississippi river. A period of prosperity now set in. Civil in place of military government was instituted; immigration began; and Andrew Turnbull, an Englishman, brought over a band of about 1,500 Minorcans (1769), whom he engaged in the cultivation of indigo at New Smyrna. Roads were laid out, some of which yet remain; and in the last three years of British occupation the Government spent \$580,000 on the two provinces. Consequently, the people of Florida were for the most part loyal to Great Britain during the War of American Independence. In 1776, the Minorcans of New Smyrna refused to work longer on the indigo plantations; and many of them removed to St. Augustine, where they were protected by the authorities. Several plans were made to invade South Carolina and Georgia, but none matured until 1778, when an expedition was organized which co-operated with British forces from New York in the siege of Savannah, Georgia. In the following year, Spain having declared war against Great Britain, Don Bernardo de Galvez (1756-94), the Spanish governor at New Orleans, seized most of the English forts in West Florida, and in 1781 captured Pensacola.

Reversion to Spain.—By the Treaty of Paris in 1783 Florida reverted to Spain, and, no religious liberty being promised, many of the British inhabitants left East and West Florida. A dispute with the United States concerning the northern boundary was settled by the treaty of 1795, the line 31° N. lat. being established.

Cession to the U.S.A.—The westward expansion of the United States made it highly desirable to have American ports on the Gulf of Mexico; consequently, the acquisition of West Florida as well as of New Orleans was one of the aims of the negotiations which resulted in the purchase of Louisiana in 1803. After the cession of Louisiana to the United States, the people of West Florida feared that that province would be seized by Napoleon. They, therefore, through a convention at Buhler's Plains (July 17, 1810), formulated plans for a more effective government. When it was found that the Spanish governor did not accept these plans in good faith, another convention was held on Sept. 26 which declared West Florida to be an independent State, organized a government and petitioned for admission to the Union. On Oct. 27, President James Madison, acting on a theory of Robert R. Livingston that West Florida was ceded by Spain to France in 1800 along with Louisiana, and was therefore included by France in the sale of Louisiana to the United States in 1803, declared West Florida to be under the jurisdiction of the United

FLORIDA SCENERY

1. A scene in the Everglades, the vast swamp of southern Florida. The swamp-land, which is very fertile, is being gradually reclaimed. An Everglades drainage district of about 4,200,000 ac. was set aside by the State legislature in 1913, to be drained by a system of canals
2. A pine forest traversed by a modern improved road. Great forests of pine and cypress are numerous in Florida
3. View from the sea of Miami, in the south-eastern part of Florida, situated on the Bay of Biscayne and the Miami River. This photograph, showing new buildings in the business section, was made one year after the hurricane of 1926 which seriously damaged the greater part of the city
4. The principal port, Jacksonville, as seen from the air. Jacksonville, known as the Gate city to Florida, is in the north-eastern part of the State, on the left bank of the St. Johns River
5. Palm Beach, as seen across Lake Worth. The famous city and winter-resort is partially separated from the mainland by Lake Worth, an arm of the Atlantic. The district situated on the mainland proper is called West Palm Beach
6. Putting-green of the Bay Shore Golf Course at Miami Beach

States. Two years later the American Congress annexed the portion of West Florida between the Pearl and Mississippi rivers to Louisiana (hence the so-called Florida parishes of Louisiana), and that between the Pearl and the Perdido to the Mississippi Territory.

In the meantime war between Great Britain and the United States was imminent. The American Government asked the

CLEARING A TRAIL THROUGH THE FLORIDA EVERGLADES WITH A COMBINED TRACTOR AND COMPRESSED-AIR DRILL

Spanish authorities of East Florida to permit an American occupation of the country in order that it might not be seized by Great Britain and made a base of military operations. When the request was refused, American forces seized Fernandina in the spring of 1812, an action that was repudiated by the American Government after protest from Spain, although it was authorized in official instructions. About the same time an attempt to organize a government at St. Mary's was made by American sympathizers, and a petty civil war began between the Americans, who called themselves "Patriots," and the Indians, who were encouraged by the Spanish. In 1814 British troops landed at Pensacola to begin operations against the United States. In retaliation General Andrew Jackson captured the place, but in a few days withdrew to New Orleans. The British then built a fort on the Apalachicola river, and there directed expeditions of Indians and runaway negroes against the American settlements, which continued long after peace was concluded in 1814. In 1818 General Jackson, believing that the Spanish were aiding the Seminole Indians and inciting them to attack the Americans, again captured Pensacola. By the treaty of 1819 Spain formally ceded East and West Florida to the United States; the treaty was ratified in 1821, when the United States took formal possession, but civil government was not established until 1822.

Indian Affairs.—Indian affairs furnished the most serious problems of the new Territory of Florida. Immediately after the cession of Florida to the United States, pressure was brought to bear upon Congress and the President to have the Seminole Indians removed and the country thrown open to settlement. The Indians, who had been allowed to occupy their lands in peace by the Spaniards, could not understand why they should be forced to move to new lands west of the Mississippi; but they consented, by the Treaty of Fort Moultrie in 1823, to live within certain limits. Conflicts followed, however, as the population increased, and a new demand was made to have the Indians removed. By treaties made at Payne's landing in 1832 and Fort Gibson in 1833 the Indian chiefs agreed to exchange their Florida lands for equal territory in the western part of the United States. But a strong sentiment against removal suddenly developed, and the efforts of the United States to enforce the treaty brought on the Seminole War (1836-42), which resulted in the removal of all but a few hundred Seminoles whose descendants still live in southern Florida.

Secession.—In 1845 Florida became a State of the American Union. On Jan. 10, 1861, an ordinance of secession, which declared Florida to be a "sovereign and independent nation," was adopted by a State convention, and Florida became one of the Confederate States of America. The important coast towns were readily captured by Union forces—Fernandina, Pensacola and

St. Augustine in 1862, and Jacksonville in 1863; but an invasion of the interior in 1864 failed, the Union forces being repulsed in a battle at Olustee on Feb. 20, 1864. In 1865 a provisional governor was appointed by President Andrew Johnson, and a new State Government was organized. The legislature of 1866 rejected the Fourteenth Amendment to the Federal Constitution, and soon afterwards Florida was made a part of the Third Military District, according to the Reconstruction Act of 1867. Negroes were now registered as voters by the military authorities, and another constitutional convention met in Jan. and Feb., 1868. A factional strife in the dominant party, the Republican, threatened to break up the convention, but through the efforts of General George M. Meade the differences were reconciled. In due time a constitution was framed and was ratified by the electors, and Florida passed from a quasi-military to a full civil government on July 4, 1868.

Reconstruction.—The factional strife in the Republican party continued, a number of efforts being made to impeach Governor Harrison Reed (1813-99). The decisive year of the Reconstruction period was 1876. The canvassing board, which published the election returns, cast out some votes, did not wait for the returns from Dade county, and declared the Republican ticket elected. George F. Drew (1827-1900), the Democratic candidate for governor, then secured a mandamus from the circuit court restraining the board from going behind the face of the election returns; this was not obeyed and a similar mandamus was therefore obtained from the supreme court of Florida, which declared that the board had no right to determine the legality of a particular vote. According to the new count thus ordered, the Democratic state ticket was elected. By a similar process the board's decision in favour of the election of Republican presidential electors was nullified, and the Democratic electors were declared the successful candidates; but the electoral commission, appointed by Congress, reversed this decision. (See **ELECTORAL COMMISSION**.) In 1879 the term of Simon B. Conover, Republican senator from Florida, came to an end, and the election of Wilkinson Call placed the Democratic party in full control of the State and the State's representation in the national Congress. From that date, Florida was uniformly Democratic until 1928, when the Republicans carried the State for President and also elected a number of candidates for local offices. In 1916 a contested primary election, which grew out of a new system of voting that permitted the voter to register a first and second choice, resulted in the nomination of Sidney J. Catts, as a Prohibitionist and in his election as governor; with this exception, all of the State's executives have been Democratic. The question of prohibition played a large part in State politics until the ratification of the Eighteenth Federal (Prohibition) Amendment by the Florida legislature Dec. 14, 1918.

Drainage and Internal Improvement.—Since the Civil War Florida has devoted much attention and money to drainage and internal improvement. By an act of Congress passed in 1850, the Federal Government turned over to the State practically all of the Everglades and other lands known as swamp or overflowed lands, with the provision that all proceeds from such lands be applied to their reclamation. The board of trustees for the internal improvement fund, created in 1855, had under its control, in 1879, about 13,000,000 ac. of such land, from which grants and sales were made for the purpose of encouraging railway and drainage-canal construction. Besides the various grants made to railway companies, the trustees in 1881 sold to Hamilton Disston, of Philadelphia, 4,000,000 ac. of swamp land at 25 cents per ac., in order to raise funds for internal improvement projects. Between 1881 and 1896 a private company with large holdings in the Everglades attempted to dig a canal from Lake Okeechobee to the Gulf of Mexico, but the project had to be abandoned after overflows closed the canal in 1902. By the Drainage Act of 1905 the State board of drainage commissioners was created, with power to build canals, levees and dikes, to do other drainage work and to levy on the lands to be benefited taxes sufficient to maintain the work. Under the board's control various drainage works were started, including six canals between Lake Okeechobee and

the Atlantic ocean to be used in draining the Everglades. Little progress was made, however, until after 1910.

In order to expedite the draining of the Everglades, the legislature in 1913 created the Everglades drainage district, consisting of about 4,200,000 ac., and placed the work under a board of commissioners. According to a report of the State engineer there were, in 1924, five main canals connecting Lake Okeechobee with the Atlantic and two others were under construction. At that time 427 miles of canal, using 14 locks, were in operation. Such canals serve the double purpose of drainage and a passage way for light-draught vessels. Much remains to be done, however, before the drainage of the Everglades is an accomplished fact. The continuation of this work by the State and private interests, along with the construction of railways, has made possible the phenomenal development of southern Florida since 1920. The most outstanding feature in the recent history of the State was the great interest shown in Florida real estate during the period 1923-26, which resulted in many new developments and a consequent increase in wealth and population. This movement, however, was checked in part, in 1926, when speculation reached the point of saturation.

BIBLIOGRAPHY.—The standard history is that by G. R. Fairbanks, *History of Florida* (1871). This should be supplemented by D. G. Brinton's *Notes on the Floridian Peninsula, Its Literary History, Indian Tribes and Antiquities* (1859). One of the best recent histories is that by C. M. Brevard, *A History of Florida* (vol. 1, 1924; vol. 2, 1925). Woodbury Lowery, *The Spanish Settlements within the Present Limits of the United States* (vol. 1, 1901; vol. 2, subtitle "Florida," 1905) is useful as a guide to monographic literature. In vol. 2 of Justin Winsor's *Narrative and Critical History of America* (1884) there is an excellent chapter by J. G. Shea on "Ancient Florida," to which a bibliography is appended. R. L. Campbell, *Historical Sketch of Colonial Florida* (1892), treats at length the history of Pensacola. Useful monographs are: H. E. Chambers, *West Florida and Its Relations to the Historical Cartography of the United States* (Johns Hopkins Studies in Historical and Political Science, series 16, No. 5); W. W. Davis, *The Civil War and Reconstruction in Florida* (1913); and Herbert B. Fuller, *The Purchase of Florida, its History and Diplomacy* (1906). The published collections of documents relating to the State are Buckingham-Smith's *Coleccion de varios documentos para la historia de la Florida y tierras adyacentes* (1857); Benjamin F. French's *Historical Collections of Louisiana and Florida* (1846-75); J. T. Connor's *Colonial Records of Spanish Florida* (1925); *Mississippi Provincial Archives*, and "Florida Historical Documents" in the *Gulf States Historical Magazine*, vol. 6, pp. 199-202 (1902). Recent books of description and travel are: C. D. Fox, *The Truth about Florida* (1925); R. H. Barbour, *Let's Go to Florida* (1926); K. L. Roberts, *Florida* (1926); N. O. Winter, *Florida, the Land of Enchantment* (1918); and H. Rhodes and M. W. Dumont, *A Guide to Florida for Tourists, with a Chapter on the Inland Waterways* (1912). Physical and economic conditions are discussed in a pamphlet (591 pp.) published by the State Department of Agriculture—*Florida, a Pamphlet Descriptive of its History, Topography, Climate, Soil, etc.* (1904); *All Florida* (1926) and *Florida To-day* (1925) by the Bureau of Immigration, State Department of Agriculture; *Florida, its Climate, Soil, Productions, and Agricultural Capabilities* (U.S. Department of Agriculture, 1882); *A Preliminary Report on the Soils of Florida* (U.S. Department of Agriculture, Division of Soils, Bulletin 13, 1898); Florida Geological Survey, *6th Annual Report*, for 1912-13, which treats of the geography and vegetation of N. Florida; and the volumes of the *Fourteenth Census of the United States* (for 1920) which treat of Agriculture and manufactures. T. D. A. Cockerell's "West Indian Fauna in Florida" (*Nature*, vol. 46), L. F. De Pourtales' "Flora and Fauna of the Florida Keys" (*American Naturalist*, vol. 11), and C. F. Millsbaugh's *Flora of the Sand Keys of Florida* (1907), a Field Columbian Museum publication, are of value. (J. M. L.)

FLORIDA BLANCA, DON JOSE MOÑINO Y REDONDO, COUNT OF (1728-1808), Spanish statesman, was born at Hellin, Murcia, on Oct. 21, 1728. He was the son of a retired army officer. He studied at Salamanca and practised as an advocate. After a successful embassy to Rome, Florida Blanca succeeded Grimaldo as first minister to Charles III. He regulated the police of Madrid, reformed many abuses, projected canals, took measures for the improvement of trade and agriculture, and encouraged learning, science and the fine arts. The long-standing disputes with Portugal on the boundaries of the South American colonies were settled. An agreement signed at San Ildefonso (Oct. 1, 1771), was later followed by a treaty of alliance between the two powers signed at Pardo (Mar. 24, 1778). At the outbreak of war between Great Britain and the North American colonies,

Florida Blanca advised a middle course, but Spain was drawn into the conflict in 1779. Florida Blanca was much under the influence of French *philosophes* and economic writers. The French Revolution frightened him into reaction, and he advocated the support of the first coalition against France. He retained his office for three years under Charles IV.; but in 1792, through the influence of the favourite Godoy, he was dismissed and imprisoned in the castle of Pampeluna. Here he was saved from starvation only by the intervention of his brother. He remained in seclusion till the French invasion of 1808. He was then nominated president of the central junta at Aranjuez. He died at Seville on Nov. 20 of the same year. He left several short treatises on jurisprudence.

See *Obras originales del Conde de Floridablanca*, edited, with biographical introduction, by A. Ferrer del Rio, in the *Biblioteca de Rivadeneyra*, vol. lix.; and authorities quoted under CHARLES III. of Spain.

FLORIDOR [JOSIAS DE SOULAS, Sieur de Prinefosse] (d. c. 1671), French actor, was born in Brie early in the 17th century, the son of a gentleman of German family who had moved to France. The son entered the French army, but left it for the theatre, where he took the name of Floridor. His first Paris appearance was in 1640. Three years later he joined the company at the Hôtel de Bourgogne, where he played all the leading parts in tragedy and comedy and became the head of his profession. He was a man of superb physique and excellent carriage, with a flexible and sonorous voice, and manners of rare distinction and elegance. Louis XIV. held him in particular esteem.

FLORIN, the name of several coins of the continent of Europe and of two coins struck in England at different times. The word comes through the Fr. *florin* from the Ital. *florino*, flower, Lat. *flos*, *florem*. Fiorino was the Italian name of a gold coin issued at Florence in 1252, weighing about 54 grains. This coin bore on the obverse a lily, from which it took its name of "the flower," on the reverse the Latin name of the city *Florentia*, from which it was also known as a "florence." "Florin" and "florence" seem to have been used in English indiscriminately as the name of this coin. The Florentine florin was held in great commercial repute throughout Europe, and similar coins were struck in Germany, other parts of Italy, France, etc.

The English gold florin was introduced by Edward III. in 1343, half and quarter florins being struck at the same time. This gold florin weighed 108 grains and was to be current for six shillings. It was found, however, to be over-valued in proportion to the silver currency and was demonetized the following year. The florin did not appear in the English coinage until 1849, when silver coins with this name, having a nominal value of two shillings (one-tenth of a pound) were struck. In 1887 a double florin or four-shilling piece was issued, but its coinage was discontinued in 1890. (See also NUMISMATICS.)

FLORIO, GIOVANNI (1553?-1625), English writer, was born in London about 1553. He was of Tuscan origin, his parents being Waldenses who had taken refuge in England from persecution. In 1578 he published a work entitled *First Fruits*, which was accompanied by *A Perfect Induction to the Italian and English Tongues*. It was dedicated to the earl of Leicester. Three years later Florio was admitted a member of Magdalen college, and became a teacher of French and Italian in the University of Oxford. In 1591 appeared his *Second Fruits*, to which was annexed the *Garden of Recreation, yielding six thousand Italian Proverbs*. These manuals contained an outline of the grammar, a selection of dialogues in parallel columns of Italian and English, and longer extracts from classical Italian writers in prose and verse. Florio's Italian and English dictionary, entitled *A World of Words*, was published in folio in 1598. After the accession of James I, Florio was French and Italian tutor to Prince Henry, and afterwards to the queen. His *magnum opus* is the admirable translation of the *Essays on Morall, Politike, and Millitarie Discourses of Lo. Michaell de Montaigne*, published in folio in 1603 in three books, each dedicated to two noble ladies. A second edition in 1613 was dedicated to the queen. Special interest attaches to the first edition from the circumstances that, of the several copies in the British Museum library, one bears the autograph of

Shakespeare—long received as genuine but now supposed to be by an 18th century hand—and another that of Ben Jonson. This is one of the most famous of all translations, and, like all the great ones, cannot be called faithful to the letter of the original. Full of idiomatic turns of phrase, and even of words of his own invention, it does not so much render Montaigne as make him live in the new language. It was suggested by Warburton that Florio is satirized by Shakespeare under the character of Holoternes in *Love's Labour's Lost*. He married the sister of the poet Daniel, and had friendly relations with many writers of his day. Ben Jonson sent him a copy of *Volpone* with the inscription, "To his loving father and worthy friend, Master John Florio, Ben Jonson seals this testimony of his friendship and love." He died at Fulham, London, in the autumn of 1625.

His translation of the *Essays* was issued (1892-93) in the Tudor Translations Series.

See C. P. de Chambrun, *Shakespeare et Florio* (1916); L. Chambrun, *Giovanni Florio* (1921).

FLORIS, FRANS, or more correctly FRANS DE VRIENDT, called FLORIS (1520-1570), Flemish painter. Son of a stone-cutter, Cornelis de Vriendt, who died at Antwerp in 1538, he began life as a student of sculpture, but afterwards gave up carving for painting. At the age of 20 he went to Liège and studied with Lambert Lombard. Following in the footsteps of Mabuse, Lambert Lombard had visited Florence, and caught the manner of Salviati and other pupils of Michelangelo and Del Sarto. It was about the time when Schoreel, Coxie and Heemskerck, after migrating to Rome and imitating the masterpieces of Raphael and Buonarroti, came home to execute Dutch-Italian works beneath the level of those produced in the peninsula itself by Leonardo da Pistoia, Nanaccio and Rinaldo of Mantua. Fired by these examples, Floris in his turn wandered across the Alps and appropriated without assimilation the various mannerisms of the schools of Lombardy, Florence and Rome. He came home and joined the guild of Antwerp in 1540. He is known to have illustrated the fable of Hercules in ten compositions, and the liberal arts in seven, for Claes Jongeling, a merchant of Antwerp, and adorned the duke of Arschot's palace of Beaumont with 14 colossal panels. The earliest extant canvas by Floris is the "Mars and Venus ensnared by Vulcan" in the Berlin museum (1547), the latest a "Last Judgment" (1566) in the Brussels gallery. Floris owed much of his repute to the cleverness with which his works were transferred to copper by Jerome Cock and Theodore de Galle. He was engaged on a Crucifixion and a Resurrection for the grand prior of Spain when he died on Oct. 1, 1570, at Antwerp.

FLORUS, Roman historian, flourished in the time of Trajan and Hadrian. He compiled, chiefly from Livy, a brief sketch of the history of Rome from the foundation of the city to the closing of the temple of Janus by Augustus (25 B.C.). The work, which is called *Epitome de T. Livio Bellorum omnium annorum DCC Libri duo*, is a rhetorical panegyric of the greatness of Rome. Though often wrong in geographical and chronological details, it was much used in the middle ages. In the mss. the writer is variously given as Iulius Florus, Lucius Annaeus Florus, or simply Annaeus Florus. From certain similarities of style he has been identified with Publius Annii Florus (q.v.) author of a Virgilian dialogue, of which the introduction has been preserved.

The best editions are by O. Jahn (1852), C. Halm (1854), which contain the fragments of the Virgilian dialogue. There is an English translation in Bohn's *Classical Library*.

FLORUS, IULIUS, poet, orator, and jurist of the Augustan age. Horace dedicated to him two of his *Epistles* (i. 3; ii. 2), from which it would appear that he composed light lyrics. The statement of Porphyry, the old commentator on Horace, that Florus himself wrote satires, is probably erroneous, but he may have edited selections from the earlier satirists (Ennius, Lucilius, Varro). He was one of the young men who accompanied Tiberius to Armenia. He has been variously identified with Iulius Florus, orator and uncle of Quintilian's friend Iulius Secundus (*Instit.* x. 3, 13); with the leader of an insurrection of the Treviri (Tacitus, *Ann.* iii. 40); with the *Postumus* of Horace (*Odes*, ii. 14) and even

with the historian Florus.

FLORUS, PUBLIUS ANNIUS, Roman poet and rhetorician, identified by some authorities with the historian Florus (q.v.). The introduction to a dialogue called *Virgilius orator an poeta* is extant, in which the author (whose name is given as Publius Annii Florus) states that he was born in Africa, and at an early age took part in the contest of poets instituted by Domitian in honour of Capitoline Jove. Having been refused a prize owing to the prejudice against African provincials, he left Rome and after travelling for some time set up at Tarraco as a teacher of rhetoric. But he must have returned to Rome, for it is agreed that he is the Florus who wrote the lines quoted, with Hadrian's answer, by Spartianus (*Hadrian* 16). Twenty-six trochaic tetrameters, *De qualitate vitae*, and five graceful hexameters, *De rosis*, are also attributed to him. Florus is important as being the first in order of a number of second century African writers who exercised a considerable influence on Latin literature, and also the first of the *poetae neoterici* or *novelli* (new-fashioned poets) of Hadrian's reign, whose special characteristic was the use of lighter and graceful metres (anapaestic and iambic dimeters), which had hitherto found little favour.

The little poems will be found in E. Bährens, *Poetae Latini minores* (1879-83); for an unlikely identification of Florus with the author of the *Pervigilium Veneris* (q.v.) see E. H. O. Müller, *De P. Annio Floro poeta et de Pervigilio Veneris* (1855) and, for the poet's relations with Hadrian, F. Eyssenhardt, *Hadrian und Florus* (1882); see also F. Marx in Pauly-Wissowa's *Realencyclopädie*, i. pt. 2 (1894).

FLOTATION: see COMPANY PROMOTION.

FLOTATION PROCESS: see METALLURGY.

FLOTOW, FREIHERR FRIEDRICH FERDINAND ADOLF VON (1812-1883), German operatic composer, was born on his father's estate at Teutendorf, Mecklenburg, on April 27, 1812. His first real success was in Paris with *Le Naufrage de la Méduse* at the Renaissance Théâtre in 1838. Greater success, however, attended his later works, *Alessandro Stradella* (1844), *Martha* (Vienna, Nov. 25, 1847), *Die Grossfürstin* (1850), *Indra* (1853), *Rübezahl* (1854), *Hilda* (1855), *Albin* (1856) and *L'Ombre* (1870). He died on Jan. 24, 1883, at Darmstadt.

See *Friedrich von Flotows Leben* (1892), by his widow.

FLOTSAM, JETSAM and LIGAN, in common law, goods lost at sea, as distinguished from goods which come to land, which are technically designated *wreck* (q.v.). Jetsam (the same word as *jettison*) is when goods are cast into the sea and there sink and remain under water; flotsam is where they continue floating on the surface; ligan (or *lagan*) is where they are sunk in the sea, but tied to a cork or buoy in order to be found again. Flotsam, jetsam and ligan belong to the sovereign in the absence only of the true owner. Wreck, on the other hand (i.e., goods cast on shore), was by the common law adjudged to the sovereign in any case, because it was said by the loss of the ship all property was gone out of the original owner. (See *WRECK*.)

FLOUNDER, a name given generally to flat fishes, other than soles, and in England particularly to *Pleuronectes flesus*, which range from northern Europe to the Mediterranean, and often enter fresh water. *P. stellatus* of the Pacific coast of North America is a related species. In America the name is given to several species of flat fish, e.g., the winter flounder (*Pseudopleuronectes americanus*) and the summer flounder (*Paralichthys dentatus*).

FLOUR AND FLOUR MANUFACTURE. Flour is defined as the fine, clean, sound product made by bolting wheat meal. The word is used in a less definite sense of other cereals and even non-cereals or other substances in a finely powdered state, though in these cases it is usual to use such terms as bean, rice, potato or other flour. The term so defined is generic and covers a wide range of products differing by reason of the variety or form of wheat used in their manufacture, or by reason of certain distinctive qualities required for several purposes.

The modern miller usually provides many types and grades of flour, each in the highest degree suitable for certain purposes. This specialization has led to the modification of older milling processes and the adoption of new ones, to meet the demands for cleaner, whiter and better bread-stuffs, as well as owing to the

necessity for producing these better flours from wheats differing fundamentally from those available 50 years ago.

Bread Flours.—As compared with wheat-flour, all other materials used for making bread are of secondary importance. Rye bread is consumed in some of the northern parts of Europe and is popular in many parts of the United States, and breads commonly called corn-pone, hoe-cake, Johnny cake, made from corn-meal are largely eaten in the Southern States and less generally throughout the corn belt. In southern Europe the meal of various species of millet is used and in India and China durra and other cereal grains are baked for food. Buckwheat is employed in Russia, Holland and the United States, and in South America the meal of the tapioca plant; the flour of peas, beans and other leguminous seeds is also baked in cakes. But, excepting rye, none of these substances is used for making vesiculated or fermented bread, for only wheat and rye yield flours which, mixed with water, form doughs capable of satisfactory aeration or leavening.

Aside from its high nutritive value, due to its starch and gluten or protein content, and to a less degree to the mineral substances present, the most important characteristic of wheat flour is its capacity, when made into a dough, to enmesh gas, thus forming an open-textured, spongy, light bread. The gas formed either by the use of yeast as a leavening agent, or by the chemical reaction between an acid ingredient and bicarbonate of soda, is carbon dioxide (CO_2). Gas required for inflating the dough is produced by the growth of yeast. Yeast is a plant requiring food, and it must have sugar, nitrogenous matter and mineral salts in forms which it can assimilate; all flours contain some of these necessary yeast foods. They also contain certain enzymes, which may be called generically diastase. When dough is made these enzymes begin to operate on the starch of the flour, converting some of it, by stages, into sugar. The limiting factor in the quantity of gas evolved during panary fermentation is frequently a shortage of yeast-food; for example, the quantity of pre-existing sugar is insufficient, particularly if the proportion of yeast used is substantial and a prolonged fermentation is required. Therefore the yeast depends largely, and in the later stages of fermentation exclusively, for its saccharine food on the sugar produced in the dough by diastatic action. Modern bakery practice, in which all the operations between the mixing of the dough and the removal of the bread from the oven are performed to a definite time schedule, will not wait on the development of sugar in sufficient quantity to feed the growing yeast. Under certain conditions the addition of sugar or of special sugars made from corn starch is good practice, but it is preferable to use a highly diastic malt extract which produces sugar as the yeast uses it; in any case the yeast requires a sufficiently mixed food which includes some form of assimilable nitrogenous matter. (See BREAD and BREAD MANUFACTURE.)

Baking Powder Leavening Agents.—Much of the bread baked in the home is of the hot bread or biscuit variety and is made by adding chemical leavening agents to the flour and water, or milk mixture. Baking powders are used in very large quantities in the production of biscuits, cakes and special forms of bread commonly known as doughnuts, pancakes, etc. The formulae for baking powders vary somewhat, but all depend upon the release of carbon dioxide.

TYPES OF FLOUR

Self-rising Flour.—In recent years millers have added the chemical reagents necessary to the evolution of carbon dioxide gas directly to their flour. The proportion of the alkaline body, bicarbonate of soda, is generally 1% of the flour. Theoretically, a quantity of the acid body should be used just sufficient to neutralize the bicarbonate of soda; but in practice it is desirable and usual to use slightly more of the acid body. In 1928 the acid substance used, in self-rising flours is generally acid phosphate of lime. In recent years the manufacture of this chemical product

FIG. 1.—MILLSTONE FOR GRINDING WHEAT

has been very greatly improved and it is now excellent as to purity and constitution. When the finished self-rising flour contains 1% of bicarbonate of soda, from 1½% to 2½% of this phosphate should be used.

In the making of bread the growth of the yeast and the evolution of gas was a relatively long process, ranging from 3 to 20 hours. Modern practice has, however, speeded up the fermentation process until the usual period of gas production is not more than four hours. While these processes are proceeding the flour as dough is being gradually rendered capable of easy distension and gas retention. It follows that the constitution and characteristics of the flour used must conform to the conditions as to time, temperature and proportion of yeast used: so that there is no fixed standard of excellence in flour which can be always measured by any known factor, e.g., the percentage of nitrogenous matter insoluble in water. On the contrary, widely differing characteristics are required, which the miller, as a specialist, must know and satisfy. So far as self-rising flour is concerned, he knows that the evolution of gas is rapid, and that the flour as dough must be capable of rapid distension and good gas retention. Therefore the wheats used in the manufacture of such flour differ substantially from those used for the manufacture of bread flours; and even in the manufacture of the latter regard must be paid to the conditions of time and temperature and to the sort and proportion of yeast used. These considerations have led to many refinements of manufacture and to the most modern developments of milling.

In Great Britain the type of bread-stuff consumed has changed to a substantial extent and has been affected by the increase in the number of tea-shops and the growth of the "tea" habit; that is to say, while the consumption of bread per head of the population has declined, the consumption of cakes, scones and "small goods" has greatly increased. The consumption of flour and wheatmeal per head of the population appears to have been stationary in recent years in Great Britain, and stands at 227 lb. per head of the population per annum. In the United States until 1900 this was also true, standing at about 224 lb., but then it declined and seems now to be about 176 pounds. In France the figure appears to be much higher than in either Great Britain or America.

Brown Bread Flours.—The consumption of brown bread or whole-wheat bread appears to have varied little in recent years, although there is at present more interest in whole-wheat breads. "Wheatmeal" is not defined in Great Britain. It may be the entire product obtained by grinding cleaned wheat, and if designated whole wheatmeal it should be the 100% article; but it is usual and legitimate to describe as wheatmeal either the 100% article or the product from which bran equalling 5% to 10% of the whole has been abstracted. In the United States the nomenclature used is different. There the 100% is called Graham flour and the terms whole-wheat or entire wheat-flour connote a meal from which a portion of the bran has been removed.

Numbers benefit by the presence of bran or "roughage" in their food, and a proportion of whole-wheat bread is widely recommended. During the World War it was ascertained that brown flours formed 5% of the total flours consumed in Great Britain. This group of bread-stuffs comprises certain well-known proprietary flours that are not whole-meal, and it is safe to say that wheatmeals then formed only from 2% to 3% of the total flours consumed. There is no reason to think (1928) that this proportion has been substantially increased either in Great Britain or the United States. Wholemeals remain much discussed.

Biscuit Flours.—For the manufacture of biscuits (crackers) certain types of flour are required, which differ materially from those used for bread. There are very many kinds of biscuits, and specialization as to the types of flour required for them is carried to great lengths.

WHEAT

Wheat as Raw Material.—The embryo or germ from which the new plant originates forms from 1½% to 2% of the wheat berry. The endosperm is the food upon which the young plant lives till it is able to obtain its sustenance from the soil and air. The endosperm in its original form cannot, however, be assim-

lated by the embryo, and certain enzymes in the presence of moisture gradually bring about the necessary changes. As a consequence the endosperm becomes liquid, and the bran functions as a container to it. This bran is very resistant to disintegration and can be found in the soil as an empty sac weeks or months after sowing.

The miller essentially divides wheat into two products, flour and offal, though there are several grades of each. The embryo or germ is sometimes regarded as a third product, but actually it goes into the two named. Until modern methods of milling were invented it was never obtained as a separate product, and even to-day it is impossible to separate more than about $\frac{1}{4}$ of the whole, that is to say, more than about $\frac{1}{4}$ of the 2% contained in the wheat berry. Germ, because of its oily nature, is particularly resistant to disintegration. Pressure applied either by millstones or rolls may flatten the particles and express some of its oil from the germ into the flour; but it is an error to suppose that flours manufactured by millstones contained the germ, and that those manufactured by modern methods do not. Formerly the germ went mainly or wholly into the by-products; to-day some of it is extracted as substantially a separate product and is added, after cooking (which is necessary), to white flour to form certain special flours, *e.g.*, Hovis, a well known English product. The remainder goes mainly or wholly into the by-products of milling. Flours containing raw germ will not remain sound under trying conditions for a considerable period. The enzymes provided by nature to convert the endosperm into plant food reside mostly in or near the embryo or germ, and their activities have to be controlled or nullified in preparing the germ for use in bread; but ways have been devised whereby to some extent it can be included in certain flours.

Wheats and the Wheat Berry.—There are several races and very many varieties of wheat, some hard, some soft: some possessing so-called red bran, others white bran; some yielding white flours, others yellow flours; some growing and maturing rapidly, others slowly. On arrival at the mill their moisture content varies from 9% to, say, 20%. Natural conditions of soil and climate enter into the selection of the varieties chosen for cultivation, and when a mill is situated in a great wheat-growing district the types of wheat available for its economic use may not differ widely; nevertheless, there are diversities in their constitution and character. But when, as in Great Britain, the wheats come from all parts of the world in an irregular supply, the miller has somehow to manufacture flours of regular quality from raw material of very great diversity.

The miller divides the berry essentially into two products, flour and branny husk. The bran is made up of several layers. For present purposes it is unnecessary to deal with other than two of them. The outer skin (epidermis) is, to some extent, sepa-

FIG. 2.—MILLSTONES: RUNNER AND BEDSTONE FACE

rated from the inner layers during the processes of milling, and is the principal constituent of the material known to millers as "bee's wing," a name indicative of its appearance. This bee's wing has a very high fibre content and is of low or little food value.

On the inner side of the bran there is a layer of rectangular cells known as the aleurone cells, of higher nutritive value than the bran. Theoretically wheat should yield much more flour than millers usually extract. Hence, if any attempt were made in commerce to increase the extraction, it is the inner side of the branny husk which should be attacked, not the outer one. When wheat was passed between millstones, it was principally the epi-

dermis which was removed and passed as bran powder into the flour; the aleurone cells were left then, as they are now, on the finished bran. The addition of such powdered material to flour darkened it and had some effect in lowering its food value.

All wheats, moreover, have a crease. This greatly impedes an easy and satisfactory separation of wheat into its component commercial parts. It is also a receptacle for dust and dirt. In the early days of modern milling, millers attempted to split each berry down the crease and obtained a very dark product known as crease flour or crease dirt. This attempt proved to be a failure. A pair of fluted rolls, 60 in. long, grinds as a normal feed about 50,000,000 berries of wheat per hour, and it proved impossible to split each berry, or even most of them, in the desired way. Instead, wheat washing was introduced. The berry, furthermore, is furnished at one end with "hairs of beard" (which must not be confounded with the awns attached to the glumes), and these hairs have also to be removed by the miller.

Constitution of Flour.—The chemical constitution of flour may be stated as follows:—

Starch	65 to 70%
Proteins	9 to 14%
Cellulose and fat	1%
Sugars	2½%
Mineral matter (ash)	1%
Water	13 to 15%

Actually, in exceptional cases, there are deviations beyond these limits. The principal proteins are gliadin and glutenin. When flour is made into a dough these two proteins constitute at least 80% of the material known as gluten. They are colloidal bodies and are of the greatest importance. It is wrong to say that very white bread is pure starch or relatively very starchy, for colour of crumb is largely due to the refraction and reflection of light, and the crumb of a loaf to be very white and bright must be well aerated; without a substantial or large proportion of these proteid bodies satisfactory aeration is impossible.

The proportions of cellulose and ash present in flour are largely under the control of the miller. The cellulose is sometimes described as woody fibre, and by excluding particles of branny husk the proportion present of this indigestible matter is low. The ash consists principally of phosphates of potash and to a much smaller extent of phosphates of magnesia and lime, with traces of other constituents. The proportion of ash may be as low as 0.35% in the highest grades of flour or may rise to, say, 1% in the commercially lowest grades. In no case is the presence of calcium salts of substantial significance, and this applies to wheatmeals also. The form in which these constituents are combined in wheat has not been definitely ascertained, but if such salts may be divided into two groups, organic and inorganic, they are at that stage mainly or wholly organic, but become largely inorganic as a result of inorganic action during the milling and bread making processes.

MILLING PROCESSES

Milling processes may be conveniently divided into two stages, (1) the cleaning and conditioning of wheat and (2) the separation of husk from kernel. Stated in these terms, milling may appear to be a simple process; actually it is a complicated one and, although modern milling developments have been in the direction of simplification, the diagram or flow sheet of a large modern mill would probably be unintelligible except to those trained in the technics of milling. From the economic or technical point of view the amount added by milling to the value of the raw material is the measure of the merit of the work involved.

Wheat Cleaning and Conditioning.—The extraneous matter found in wheat consists principally of other cereals, seeds of many kinds, shapes and sizes, stones, chaff, straw, dust and dirt (earth). To extract these, many devices are employed. Sieves of perforated metal can extract substances either larger or smaller than wheat. But wheats differ so much as to size and shape of berry that better instruments than sieves are also necessary. Cylinders covered on their inner side with holes of varying sizes bored in zinc provide means of making more precise separations. Discs so bored rotating in a body of wheat are also employed.

Ascending currents of air capable of precise regulation are passed through descending showers of wheat, and carry away particles which by reason of their shape or compactness of particle can be so separated. Wheat is scoured and brushed in various ways. One well-known machine consists essentially of a cylinder, clothed on its inner side with emery; beaters revolving on a shaft serve the double purpose of scouring the wheat against the emery surface and of passing it through the length of the cylinder.

FIG. 3.—HALF CROSS-SECTION DIAGONAL ROLLER MILL (ENGLISH PRACTICE)

Conditioning is an English term; in the United States a somewhat similar operation is called tempering. Essentially it means that the physical condition of any given wheat is adjusted so that optimum separations of husk from kernel can be made. Sometimes water is added; sometimes it is abstracted. Adjustments must be made to suit the wheat under treatment, the conditions as to atmosphere and milling machinery subsequently used, and the flours to be produced. The factors employed are water, time and temperature. The methods of conditioning are still in the process of evolution. The results obtained by conditioning are mainly or wholly physical.

Grinding.—Roller mills are almost invariably employed for grinding to-day. When millers attempted at one operation to perform the whole of the grinding required, millstones were employed. This involved the use of friction, very great in amount and intensity: one passage between millstones involved at least 4 ft. of rough handling. Even when the wheats used were soft or mellow and therefore relatively resistant to disintegration, some of the husk of the wheat was reduced to powder. The Hungarians grew wheat of excellent quality, but the grain was hard and its skin friable. They therefore began, about 60 years ago, to use roller mills. In other parts of Europe and in the eastern United States the wheats available were then mellow and the necessity for relatively gentle grinding was not great. But when the States of the north-west and the western provinces of Canada were developed, the varieties of wheat found to be suitable were hard and had friable skins. Hence the American millers adopted the new Hungarian methods and British millers were compelled to follow suit, for the ultimate users and consumers of flour would not accept flour or bread containing a large proportion of powdered husk. For these reasons gradual reduction by roller mills superseded the sudden death methods of grinding wheat by millstones.

A pair of cylindrical rollers, running at the point of contact in the same direction, nip and grind their feed at one point only in their circumferences. But a release of endosperm particles

from the branny husk, and not mere crushing, being the object desired, the two rolls forming a pair are made to revolve at different speeds. This differential varies with the stage of milling. Furthermore, to effect optimum separations of husk from kernel it is necessary to obtain during the earlier stages of actual milling the endosperm particles in granular form. To effect this the rolls used in those stages are corrugated. The number and shape of these corrugations or flutes involve complicated technical points. The numbers range from 9 to 26 per in. of the roll's circumference. Still further to improve the separations the flutes are cut at varying angles in relation to the rolls' axes.

In conformity with the principle of gradual reduction, no attempt is made to obtain finished bran at one grinding; on the contrary, the wheat is broken down on the roller mills, known as the breaks, gradually by successive stages. These now number three, four or five; occasionally in some parts of the world six are used. Generally, millers aim to make as little flour as possible on the breaks, but some is made. The commercial article known as bran is separated from the stock, leaving the last break. The breaks as a stage of the milling process yield as finished products flour equalling from 8% to 18% of the original cleaned wheat and bran equalling from 10% to 15% of it. The remainder exists at that stage as granular products, known as middlings and semolina. These contain particles of pure endosperm, particles of pure husk and other particles consisting of endosperm with husk attached. The means of separating these constituents will be described in a succeeding paragraph.

Ultimately, to resolve these intermediate products into finished flour and finished husk (known commercially in Great Britain as offals and in North America as feed) further grinding by rolls is required. These are known technically as reduction rolls or reductions, and generally have either smooth surfaces or very fine flutes ranging from 70 to 120 per in. of the roll's circumference. The speed and differential are adjusted to the work to be done, but the principle of gradual reduction is employed at these stages also. The central idea of such grinding is a release of endosperm particles from husk. In the case of particles consisting of endosperm only, it is desirable to reduce them in size by grinding. In no case should granular particles, however fine, be merely crushed.

Bolting.—This term in modern milling has a generic significance. In its simplest form it means separating by means of a sieve. Sieves are used largely in milling; they sort by size. Frequently several sieves are superimposed one above another to form the milling machine known as the plansifter. Though the principle of the plansifter is simple, it required a generation of experiment before a machine acceptable to millers generally was developed. Another form of bolting machinery is the octagonal, hexagonal or round reel which revolves at a slow speed. Here also separations are made according to size of particle. A framework is mounted on a central slightly inclined shaft. The framework is clothed with wire or silk cloth and the material to be separated is passed into the interior of the reel, whence it passes either through the cover or over the tail end of the reel. Another form of bolting is performed by the centrifugal. In this machine there is a reel or cylinder, generally hexagonal, revolving slowly and covered with silk or wire cloth. Inside are beaters revolving quickly which are set to throw the stock against the cover and to move it longitudinally. Primarily this also performs separations according to size of particle; but to some extent it sorts according to compactness of particle. The same thing can be said of the plansifter, but any such sorting depends on a nice adjustment of sieve space to the quantity of feed treated. After each grinding, whether by break or reduction rolls, some sort of separation by one or another of these bolting methods is performed, and the divisions and sub-divisions of stock cause complexity. The meshes used vary from 10 to 140 per lineal inch.

PURIFYING AND BLEACHING

Purifying.—In a technical sense purifying connotes separations of the granular products known as semolinas and middlings according to compactness of particle. For this purpose the

machines known as purifiers have been designed and built. Before sorting by compactness of particle can be performed, sorting by size of particle is necessary, and must be carried out in great detail. There are various forms of this purification. Generally there is a sieve divided into a number of sections, each one having above it a separate air compartment. Through the sieve and each air compartment a current of air, under control as to intensity, is drawn. The best particles pass through the meshes of the sieve, some are held in suspension on the sieve and are floated over its end, others are caught in receptacles placed above the sieve.

Bleaching.—The colouring matter of both flour and carrots is carotin, though there is less of it present in flour than in carrots. As a constituent of flour it seems to serve no useful purpose, and generally consumers do not like bread which is even moderately yellow. On the other hand, some farmers prefer, for some reason or another, to grow those varieties of wheat which, on milling, yield yellow, sometimes intensely yellow, flour. If such flour be exposed to the atmosphere for a sufficient time it becomes whiter, the oxides of nitrogen which exist in the atmosphere entering into combination with the carotin to remove or diminish its yellowness. In the processes of bleaching flour this is effected by artificial means. A small current of air is pumped through a chamber in which flaming electrical discharges are produced intermittently. As a consequence, nitrogen peroxide is produced, and this, mixed with the excess air, is passed into the flour and oxidizes the colouring matter. Flour thus treated may contain up to four parts per million of residual nitrites. This process has been examined at great length in the law courts and elsewhere and found to be innocuous to the ultimate consumer of bread-stuffs. Bleached flours must however be so labeled if intended for sale in the United States.

Minute proportions of benzoyl peroxide will also bleach flour, and so will traces of nitrogen trichloride. These substances have been very closely investigated and are permitted in several countries. A departmental committee appointed by the British Ministry of Health has advised against their use but they have not been prohibited in Great Britain. The development of new processes for the bleaching of flour is still in an active state of investigation. The question of the merits of the natural aging of flour versus bleaching and the use of "chemical substances" as yeast foods or as flour or bread "improvers" or enrichment mediums will probably remain a subject of controversy until more is definitely known of the factors which determine flour quality. The physiological side of the problem has not been the subject of extensive investigation in the light of the new knowledge of nutrition, and this too will probably remain in the field of controversy until scientific opinion is more in accord. FLOUR BEETLE, a minute weevil or beetle of the *Tenebrionidae* which infests flour, meal, etc. The eggs develop rapidly from minute larvae into beetles which feed on flour and other cereals and also do considerable damage by boring holes into wood. *See COLEOPTERA.*

FLOURENS, GUSTAVE (1838–1871), French revolutionary and one of the most romantic figures of the Commune, was born on Aug. 4, son of Pierre Flourens (*see below*). Gustave was trained by his father to succeed him, and had a brilliant scientific career up till his father's death in 1867, when the Collège de France, to which his evolutionary theories and his repu-

lican opinions were equally objectionable, abruptly signified that it had no further use for his services. Flourens indignantly left the country and went to Crete, where he joined the ranks of the insurrection against Turkey. In this hard guerrilla warfare he gained his chief military experience, and acquired such prestige among the Cretans that he was chosen president of the delegation elected by Crete in 1868 to sit in the Hellenic parliament. Had it been admitted (*see TURKEY: History*), war between Greece and Turkey might well have resulted; the Greek government solved their difficulties by kidnapping Flourens and sending him to France, while they turned his colleagues back to Crete. He then carried on republican propaganda in Naples till he was imprisoned, and in France, where he was dangerously wounded in a duel with Paul de Cassagnac. At the funeral of Victor Noir (Jan. 12, 1870) he attempted with his usual impetuosity, to lead an insurrection, but was thwarted by Rochefort, Delescluze, and Blanqui (*qq.v.*): he did in fact attempt a rising on Feb. 7, which collapsed at once, and he was condemned to imprisonment in a fortified place. During the siege of Paris he was ardently patriotic and commanded, first five battalions raised in Belleville, then a corps of tirailleurs. Together with 23 other *chefs de bataillon* he overthrew the government on Oct. 31, 1870, charging it with treachery, but as he received support from no politician but Blanqui, withdrew from the hotel de ville after negotiation. On the outbreak of the Commune (March 18, 1871) Flourens was elected for the 19th and 20th *arrondissements* and made a colonel. He attempted by a personal example of bravery and devotion to diminish the incoherence and disorder around him: he exposed himself too rashly at Rueil in the sortie of April 3, was captured, and killed while a prisoner by a sabre cut from an officer.

See the Grand Dictionnaire, etc., Larousse (1869 etc.) *s.v.*

(R. W. P.)

FLOURENS, PIERRE (1794–1867), French physiologist, was born at Maureilhan, near Béziers, on April 15, 1794. After taking his M.D. at Montpellier, Flourens began physiological research in Paris and in 1822 published his *Recherches expérimentales sur les propriétés et les fonctions du système nerveux dans les animaux vertébrés*, in which he, from experimental evidence, sought to assign their special functions to the cerebrum, corpora quadrigemina and cerebellum. He was chosen by Cuvier in 1828 to deliver for him a course of lectures at the Collège de France. In 1832 a professorship of comparative anatomy was created for him at the museum of the Jardin. In 1833 Flourens, in accordance with the dying request of Cuvier, was appointed a perpetual secretary of the Academy of Sciences, and in 1838 was returned as a deputy for the arrondissement of Béziers. In 1840 he was elected, in preference to Victor Hugo, to succeed J. F. Michaud at the French Academy; and in 1846 he was created a peer of France. In 1847 Flourens directed the attention of the Academy of Sciences to the anaesthetic effect of chloroform on animals. At the revolution of 1848 he withdrew completely from political life, and in 1855 he accepted the professorship of natural history at the Collège de France. He died at Montgeron, near Paris, on Dec. 6, 1867.

Besides numerous shorter scientific memoirs, Flourens published *Expériences sur le système nerveux* (1825); *Cours sur la génération, l'ovologie, et l'embryologie* (1836); *Analyse raisonnée des travaux de G. Cuvier* (1841); *Buffon, histoire de ses travaux et de ses idées* (1844); *Fontenelle, ou de la philosophie moderne relativement aux sciences physiques* (1847); *Oeuvres complètes de Buffon* (1853); *De la longévité humaine* (1854); *Histoire de la découverte de la circulation du sang* (1854); *Cours de physiologie comparée* (1856); *De la vie et de l'intelligence* (1858); *De la raison, du génie, et de la folie* (1861); *Examen du livre de M. Darwin sur l'Origine des Espèces* (1864). For a list of his papers *see the Royal Society's Catalogue of Scientific Papers.*

FLOWER, SIR WILLIAM HENRY (1831–1899), English biologist, was born at Stratford-on-Avon on Nov. 30, 1831. He took his M.B. at London in 1851, and went out to the Crimea as assistant-surgeon. On his return he became a member of the surgical staff of the Middlesex hospital, London, and in 1861 curator of the Hunterian museum of the Royal College of Surgeons. In 1870 he also became Hunterian professor, and in 1884 was appointed to the directorship of the Natural History Museum

at South Kensington where he endeavoured to satisfy the demands of both the public and the student. He died in London on July 1, 1899. He made valuable contributions to structural anthropology and to the comparative anatomy of mammals.

His chief publications are: *Diagrams of the Nerves of the Human Body* (1861); *The Osteology of the Mammalia* (1870); *Fashion in Deformity* (1881); *The Horse: a Study in Natural History* (1890); *Introduction to the Study of Mammals, Living and Extinct* (1891); *Essays on Museums and other Subjects* (1898).

See C. J. Cornish, *Sir W. H. Flower* (1904), and R. Lydekker, *Sir William Flower* (1906).

FLOWER, a term popularly used for the blossom of a plant, and so by analogy for the finest part or aspect of anything. Here it is dealt with only botanically. The flower is characteristic of the highest group of plants—the flowering plants (Phanerogams)—and is the association of more or less leaf-like organs which are concerned with the production of the seed. In modern botany the group is often known as the seed-plants or Spermatophyta (see ANGIOSPERMS and GYMNASPERMS). As the seed develops from the ovule, fertilised by the pollen, the essential structures for seed-production are the pollen-bearer or *stamen* and the ovule-bearer or *carpel*. In comparative morphology, these are known as sporophylls because they bear the microspores (pollen-grains), developed in the microsporangia (pollen-sacs) or the megaspore, contained in the megasporangium (ovule). In the more primitive gymnosperms (*q.v.*) the micro- or mega- sporophylls are generally associated in separate cones, to which the term “flower” has been applied. But it is to more definite and elaborate structures in the higher angiosperms (*q.v.*) that “flower” generally refers.

Bracts.—Flowers are produced from flower-buds in the axils of leaves called *bracts*; “bract” is properly restricted to the leaf from which the primary floral axis arises, while leaves which arise between the bract and the flower are *bracteoles*. Their arrangement is similar to that of foliage leaves. In many cases, bracts protect the young flower, but they are sometimes undeveloped, and usually fall off early. Sometimes, especially with bracteoles, no flower-buds arise in their axils. At the base of the general umbel in umbelliferous plants is often a whorl of bracts, the *general involucre*, while *partial involucre*s or *involucels* are found at the base of the umbellules. In Compositae the involucre surrounds the heads of flowers (fig. 12). When bracts become united, the outer ones often do not produce flowers. A sheathing bract or *spathe*, enclosing one or several flowers is common among monocotyledons and may, in some palms, reach 20 ft. in length and enclose 200,000 flowers. The spathe may be coloured (*Anthurium*) or white (arum lily, *Zantedeschia ethiopica*). In grasses, the outer scales (glumes) of the spikelet are sterile bracts. Bracts may be changed into leaves (phyllody).

Inflorescence.—The arrangement of flowers on the axis is called the *inflorescence*. The primary axis of the inflorescence is the *rachis*; its branches, when present, are *peduncles*, which in turn may give rise to *pedicels*. A flower having a stalk is pedunculate or pedicellate; one with no stalk is sessile. To obviate any confusion, it is common to speak of the rachis as the *primary* floral axis, the peduncles as the *secondary* floral axes, and so on. The peduncle may be simple, bearing a single flower, or branched. When it proceeds from radical leaves, it is a *scape*. The floral axis may be shortened, as in daisy and fig, or flattened, convex or concave in form and bearing numerous flowers, as in marigold or in fig. Adhesions occasionally take place between the peduncle and the bracts, as in the lime-tree (fig. 1). The termination of the part upon which the whorls of the flower are arranged is the *receptacle*.

There are two types of inflorescence—one in which the flowers arise as lateral shoots from a primary axis, which goes on elongating, and the lateral shoots never exceed in their development the length of the primary axis beyond their point of origin; the flowers are thus *axillary* and the inflorescence is *indeterminate*. In the other type, the primary axis ends in a single flower, but lateral axes arise from the axils of bracts and repeat the process, the development of each lateral axis being stronger than that of the primary axis beyond its point of origin. The flowers are thus

terminal and the inflorescence is *definite*. In indeterminate inflorescences, the lower or outer flowers expand first (*centripetal*); in determinate inflorescences, it is the upper or inner flowers that open first (*centrifugal*). In some inflorescences (*mixed*), the primary axis has an arrangement belonging to one type, the branches one of the opposite type.

Amongst indefinite forms, the simplest is when a lateral shoot in the axil of a single foliage leaf ends in a single flower. In this case the flower is *solitary*. A more complicated inflorescence is commoner. Thus if the primary axis, as in fig. 2, is elongated and gives off pedicels ending in a single flower, a *raceme* is produced, which becomes a *panicle* if the secondary axes branch. If the lower flower-stalks are developed more strongly than the upper, and thus all the flowers are on a level, a *corymb* is formed, which may be simple (fig. 4) or branched. If the pedicels are wanting, so that the flowers are sessile, the result is a *spike*. If this bears unisexual flowers it is a *catkin*; if it becomes succulent and surrounded by a spathe it is a *spadix*, which may be simple (fig. 7) or branched. A spike with female flowers only and covered with scales, as in the hop, is a *strobilus*. In grasses there are usually numerous sessile flowers in small spikes (*spikelets*); if these are borne not on the primary but on secondary axes, they form a *panicle*.

If the primary axis is contracted, other forms result. When it is so short that the secondary axes arise from a common point and spread out as radii of nearly equal length each ending in a single flower or dividing again similarly, an *umbel* (fig. 8) is produced. If there are numerous flowers on a flattened, convex or concave receptacle, having short pedicels or none, a *capitulum* is formed, as in marigold and scabious (fig. 3). If the margins of the receptacle are developed upwards, they may ultimately give rise to the *hypanthodium* of the fig.

In compound indefinite inflorescences, the lateral shoots, developed centripetally, bear numerous bracteoles from which floral shoots arise, which may have a centripetal arrangement similar to that on the mother shoot, or a different one. Thus we may have a group of racemes arranged in a racemose manner; compound umbels as in most Umbelliferae (fig. 8); a raceme of capitula; a raceme of umbels, as in ivy, and so on.

The simplest type of definite inflorescence is where, as in *Anemone nemorosa*, the axis terminates in a single flower, no other flowers being produced on the plant. This is a *solitary terminal* inflorescence. When the primary floral axis, before ending in a flower, gives off lateral unifloral axes which repeat the process, the result is a *cyme*. A cyme with two axes is a *biparous* cyme or *dichasium* (fig. 11); with one axis, it is uniparous. In the dead-nettle (*Lamium*) the flowers arise in the axis of each foliage leaf and appear as if arranged in a whorl, but there is a central flower expanding first, and from its axis spring secondary axes bearing single flowers (fig. 10). The inflorescence is thus a dichasium and the clusters are called *verticillasters*. Where numerous lateral axes arise from the primary axis, a *cymose umbel* is produced. When these lateral axes grow strongly and develop irregularly, as in species of *Juncus*, the inflorescence is an *anthela*. In a uniparous cyme, the basal portion of the consecutive axes may become thickened and arranged more or less in a straight line, forming a false axis or *sympodium*, the inflorescence thus simulating a raceme. The uniparous cyme presents two forms; in a *scorpioid* cyme the flowers are arranged alternately in a double row along one side of the sympodium, the bracts forming another double row on the opposite side (*e.g.*, Boraginaceae). In a *helicoid* cyme, the flowers are in a single row and form a spiral round the false axis.

Compound definite inflorescences are by no means common, but in *Streptocarpus polyanthus* and in several calceolarias we probably have examples. Here we find *scorpioid cymes of pairs of flowers*, each pair consisting of an older and a younger flower.

Both the definite and indefinite types are represented in mixed inflorescences. Thus in the ragwort (fig. 12) the *heads* of flowers are developed centrifugally, while the *florets* open centripetally. Various combinations occur in different families.

FLOWER DEVELOPMENT

This chart is founded on three basic features: (A) a starting point of primitive flower structure in the buttercups (1); (B) three great centres (2), geraniums (3), and lilies (4)—each derived from the buttercup type, and (C) two main lines of development from each of these three centres. These main lines of development have resulted from the action of two great natural forces at work on the flower, namely, insects and wind. From each of the three chief centres broken dark lines indicate the course of development of

wind-pollinated flowers, while heavy dark lines show that of insect-pollinated flowers. In the lily line, for example, flower development as influenced by insects culminates in the orchids, while development influenced by the wind reaches its climax in the grasses. The most important changes in floral evolution are shown by coloured cross-lines: the first four from the bottom are concerned with insect-pollinated flowers; the upper three include wind-pollinated flowers as well

Tabular View of Inflorescences

A. Indefinite Centripetal Inflorescences.

- I. Flowers solitary, axillary, *Veronica hederifolia*.
- II. Flowers in groups, pedicellate.
 - i. Elongated form (Raceme), *Hyacinth*; (Corymb), *Prunus*.
 - ii. Contracted form (Umbel), *Cowslip*.
- III. Flowers in groups, sessile.
 - i. Elongated form (Spike), *Plantago*.
(Spikelet), *grasses*.
(Catkin), *Hazel*.
(Spadix), *Arum*.
(Strobilus), *Hop*.
 - ii. Contracted form (Capitulum), *Daisy*.
- IV. Compound Indefinite Inflorescences.
 - a. Compound Spike, *Rye-grass*.
 - b. Compound Spadix, *Palms*.
 - c. Compound Raceme, *Astilbe*.
 - d. Compound Umbel, most *Umbelliferae*.
 - e. Raceme of Capitula, *Petasites*.
 - f. Raceme of Umbels, *Ivy*.

B. Definite Centrifugal Inflorescences.

- I. Flowers solitary, terminal, *Tulip*.
- II. Flowers in cymes.
 1. Uniparous Cyme.
 - a. Helicoid Cyme.
 - (i) Elongated, *Alstroemeria*.
 - (ii) Contracted, *Wistaria corymbosa*.
 - b. Scorpoid Cyme.
 - (i) Elongated, *Forget-me-not*.
 - (ii) Contracted, *Erodium*.
 2. Biparous Cyme (including Dichasium, Cymose Umbel).
 - a. Elongated, *Cerastium*.
 - b. Contracted (Verticillaster), *Dead-nettle*.
 3. Compound definite Inflorescence. Many *Calceolarias*.

C. Mixed Inflorescences.

- Raceme of Scorpoid Cymes, *Horse-chestnut*.
 Scorpoid Cyme of Capitula, *Vernonia scorpioides*.
 Compound Umbel of dichotomous Cymes, *Viburnum*.
 Capitulum of contracted Scorpoid Cymes (Glomerulus), *Sea-pink*.
 Cyme of Capitula, *Ragwort*.

Parts of the Flower.—The flower consists of the floral axis bearing the sporophylls (stamens and carpels) usually with protective envelopes. The axis is normally contracted, no internodes being developed and the portion bearing the floral leaves, the receptacle, is frequently a conical, flattened or hollowed expansion; rarely the axis is elongated and internodes are developed. Upon the receptacle the parts of the flower are crowded, usually forming a series of whorls, the parts of which alternate, but sometimes arranged spirally, especially if the axis is elongated. In a typical flower (fig. 22) there are four distinct whorls, an outer *calyx* of *sepals*; within it, the parts alternating with those of the calyx, is the *corolla* of *petals*; next alternating with the parts of the corolla, the *androecium* of *stamens*; and in the centre, the *gynoecium* of *carpels*. Fig. 14 is a diagrammatic representation (*floral diagram*) of such a flower, supposed to be cut transversely, the parts of each whorl being distinguished by a different symbol. The sepals are usually greenish, their function is mainly protective, shielding the delicate internal organs before the flower opens. The petals are usually showy. Sometimes (usually in monocotyledons) the calyx and corolla are similar; in such cases the term *perianth* is applied, and the parts of the calyx are *petaloid*. In some cases the petals resemble sepals (*sepaloid*). In plants, as *Nymphaea alba* (fig. 21), where a spiral arrangement of floral leaves occurs, these whorls pass insensibly into each other. When both calyx and corolla are present, the plant is *dichlamydeous*; when one is absent, *monochlamydeous* (fig. 15). Sometimes both are absent (*achlamydeous*), as in willow. The stamens in their most differentiated form, consist each of a stalk, the *filament* (fig. 16) consisting of *pollen-sacs* containing the powdery *pollen* (microspores), which is ultimately discharged. The *gynoecium* or *pistil* terminates the floral axis. It consists of one or more carpels (megaspores), separate or combined (fig. 17). The pistil is composed of the *ovary* (fig. 20), the lower portion enclosing the *ovules* destined to become seeds; and the *stigma* loose cellular

tissue, the receptive surface on which the pollen is deposited and either sessile on the apex of the ovary (poppy) or separated by a prolonged *style*. The androecium and gynoecium are not present in all flowers. When both are present the flower is *hermaphrodite* and is represented by the symbol ♂. When only one is present the flower is *unisexual* or *diclinous*, and is either male (*staminate*), ♂, or female (*pistillate*), ♀. When all four whorls of leaves are present the flower is *complete*. Usually the successive whorls of the flower, disposed from below upwards or from without inwards upon the floral axis, are of the same number of parts, or are a multiple of the same number of parts, those of one whorl alternating with those of the whorl next to it.

In the more primitive types of flower the receptacle is more or less convex, and the series of organs follow in regular succession, culminating in the carpels (fig. 18). This arrangement is *hypogynous*, the other series being beneath (*hypo*) the gynoecium. In other cases, the apex of the growing point ceases to develop and the parts below form a cup around it, from the rim of which the outer members of the flower are developed (perigynous, fig. 19). In many cases this is carried further and a cavity is formed roofed over by the carpels, so that the outer members of the flower spring from the edge of the receptacle which is immediately above the ovary (epigynous, fig. 20).

Symmetry of the Flower.—When a flower consists of parts arranged in whorls it is *cyclic*, and if all the whorls have an equal number of parts and are alternate it is *eucyclic* (figs. 14, 25). In contrast to cyclic flowers are those where the parts are in spirals (*acyclic*). Flowers which are cyclic at one portion and spiral at another (as many *Ranunculaceae*) are *hemicyclic*. In spiral flowers there is usually a gradual passage from sepaloid through petaloid to staminal parts (water lily, fig. 21). In some cases the parts of one whorl are opposite or *superposed* to those of the next. The superposition of the stamens on the sepals in the *Caryophyllaceae* is due to the suppression of the petals.

A flower is *symmetrical* when each whorl consists of an equal number of parts, or when the parts of any one whorl are multiples of that preceding it. Thus, a symmetrical flower may have five sepals, five petals, five stamens and five carpels (fig. 14) or the number of any of these parts may be a multiple of five. In the staminal whorl especially it is common to find additional rows. In fig. 24 the parts are in fours; in figs. 25 and 26, in threes. The floral envelopes are rarely multiplied. Flowers in which the number of parts in each whorl is the same are *isomerous*; when the number in some whorls is different, the flower is *anisomerous*. It often happens that when fully formed, the number of parts in the pistillate whorl is not in conformity with that in the other whorls. In such circumstances a flower is called *symmetrical*, provided that the other whorls are normal (fig. 27). A flower in which the parts are arranged in twos is *dimerous*; in threes, fours or fives, *trimerous*, *tetramerous* or *pentamerous* respectively. Trimerous symmetry is the rule in the monocotyledons, pentamerous the commonest in the dicotyledons, though dimerous and tetramerous flowers also occur in the latter group.

The various parts of the flower have a definite relation to the central axis. Thus in a tetramerous flower, one sepal may be next the axis (superior or posterior), another next the bract (inferior or anterior) and the other two *lateral* (fig. 24). A plane passing through the anterior and posterior sepals and through the floral axis is the *median* plane of the flower; a plane cutting it at right angles and passing through the lateral sepals, is the *lateral* plane; whilst the planes which bisect the angles formed by the lateral and median planes are *diagonal* planes. In a pentamerous flower one sepal may be superior (*Rosaceae* and *Labiatae*) or inferior (pea family, figs. 28, 29); in the latter case the odd petal (*vevillum*) is then superior. In the *Scrophulariaceae* one of the two carpels is posterior, the other anterior, whilst in the *Convolvulaceae* the carpels are lateral.

When the different members of each whorl are alike, the flower is *regular*; differences in size and shape of the parts of a whorl make the flower *irregular* (fig. 28). When a flower can be divided by a single plane into two similar parts it is *zygomorphic* (as in *Papilionaceae*). Polysymmetrical flowers have a radial sym-

BRITISH WILD FLOWERS

This group contains many of the most widely known and best beloved flowers of British waysides, fields and woods, all woven into the life and literature of the nation. Shakespeare, for example, sang of the oxlip and honeysuckle; Keats, of the poppy and foxglove; Shelley, of

the anemone; Campbell, of the hyacinth; Coleridge, of the wild rose; Heber, of the Scotch bluebell; Burns, of the daisy and hawthorn; Hogg, of the purple heather; and Alfred, Lord Tennyson, of the forget-me-not

1. Honeysuckle (*Lonicera Periclymenum*). 2. Foxglove (*Digitalis purpurea*). 3. Hawthorn (*Crataegus Oxyacantha*). 4. Harebell, Bluebell of Scotland (*Campanula rotundifolia*). 5.

Bluebell, Wild Hyacinth Oxlip, a species similar to the Cowslip. 7. Heather (*Erica cinerea*). 8.

(*Scilla festalis*). 6. to the Cowslip. 7. 8. Red or Field Poppy

(*Papaver Rhoeas*). 9. Forget-me-not (*Myosotis scorpioides*). 10. English Daisy (*Bellis Perennans*). 11. Wild Rose (*Rosa canina*). 12. Wood Anemone (*Anemone nemorosa*)

metry and can be divided by several planes into similar portions; such are all regular, symmetrical flowers. When the parts of any whorl are not equal to, or some multiple of, the others, the flower is *asymmetrical*. This alteration in the symmetrical arrangement has been traced to *suppression* or *non-development* of parts, *degeneration* or imperfect formation, *cohesion* or union of parts of the same whorl, *adhesion* or union of parts of different whorls, *multiplication* of parts and *deduplication* (*chlorosis*) or splitting of parts. Cultivation has a great effect in causing changes in the various parts of a plant. The changes in colour and form of flowers thus produced are endless.

As a convenient method of expressing the arrangement of the parts of a flower, *floral formulae* have been derived. The following is a simple mode: the whorls are represented by the letters *S* (sepals), *P* (petals), *A* (stamens), *C* (carpels) and a figure marked after each indicates the number of parts in that whorl. Thus *S5P5A5C5* means that the flower is perfect, isomeric and pentamerous. The flower of *Sedum* (fig. 22) would be represented by *S5P5A5+5C5*, where *A5+5* indicates that the staminal whorl consists of two rows of five parts each.

Aestivation.—The manner in which the parts are arranged in the flower-bud with respect to each other before opening is the *aestivation* or *praefloration*, and distinctive names have been given to the different arrangements exhibited, both by the leaves individually and in their relation to each other. As regards each leaf of the flower, it is either spread out, as the sepals in the bud of the lime-tree, or folded upon itself (conduplicate), or slightly folded inwards or outwards at the edges, as in the calyx of some species of *Clematis*, or rolled up at the edges (involute or revolute), or folded transversely, becoming *crumpled* or *corrugated* as in the poppy.

When the parts of a whorl are in an exact circle, and are applied to each other by the edges only, without overlapping or folding, aestivation is *valvate*. The edges of each of the parts may be turned inwards (induplicate) or outwards (reduplicate). When the parts of a single whorl are placed in a circle, each of them exhibiting torsion so that by one of its sides it overlaps its neighbour, whilst its side is overlapped in like manner by that standing next to it, aestivation is *twisted* or *contorted*. When the flower expands, traces of twisting sometimes remain. These forms of aestivation occur in cyclic flowers and are included under *circular* aestivation. In spiral flowers the leaves may cover each other partially, like tiles on a house, or the parts may envelop each other completely (*convolute*). When the parts are five, as in many dicotyledons, there may be two parts external, two internal and a fifth which partially covers one of the inner parts by its margin and is in turn partially covered by one of the external parts (*quincuncial*), as in the corolla of *Rosaceae*. In the *Leguminosae*, the vexillum is often large and folded over the others (*vexillary*) or the carina may perform a similar office (*carinal*). Circular aestivation is generally associated with a regular calyx and corolla while spiral aestivation is connected with irregular as well as regular forms.

FLORAL ENVELOPES

Calyx.—The sepals are sometimes *free* or separate from each other, at other times united to a greater or less extent; in the former case, the calyx is *polysepalous*, in the latter *gamosepalous* or *monosepalous*. The divisions of the calyx are usually entire, but occasionally are cut (rose); rarely they are stalked. Sepals are generally more or less oval, elliptical or oblong, with blunt or acute apices. They may be erect or reflexed, spreading downwards (*divergent* or *patulous*) or arched inwards (*connivent*). They are usually greenish (*herbaceous*) but sometimes they are coloured (*petaloid*). The vascular bundles sometimes form a prominent mid-rib, at other times, several ribs. The venation is useful as pointing out the number of leaves in a gamosepalous calyx. A polysepalous calyx with three sepals is *trisepalous*, with five, *pentasepalous*, etc. The sepals are occasionally of different forms and sizes. The number of members in a gamosepalous calyx is usually marked by divisions at the apex, which may be simple projections or may extend down as fissures, the calyx

being *trifid* (three-cleft), *quinquefid* (five-cleft), etc.; or they may reach nearly to the base, the calyx being *tripartite*, *quinquepartite*, etc. The union of the parts may be complete and the calyx entire or *truncate*. The cohesion is sometimes irregular; thus a two-lipped or *labiate calyx* arises. Occasionally certain parts of the sepals are enlarged to form a spur as in *Tropaeolum*, *Viola* and *Pelargonium*. Degeneration may take place so that the calyx becomes dry and scaly (*Juncaceae*); or hairy (*Compositae*); or a mere rim (madder), when it is *obsolete* or *marginate*. In *Compositae*, the calyx is attached to the pistil and its limb is developed into hairs (*pappus*). The calyx sometimes falls off before the flower opens, as in poppies (*caducous*, fig. 36); or with the corolla, as in *Ranunculus* (*deciduous*), or it remains after flowering (*persistent*) as in *Labiatae*, or its base only is persistent (*operculate*). The receptacle bearing the calyx is sometimes united to the pistil and enlarges to form part of the fruit (apple), in which case the withered calyx is seen at the apex. Sometimes a persistent calyx encloses the fruit without being incorporated with it (*acrescent*); or it may become *inflated* or *vesicular* (*Lychnis*).

Corolla.—The corolla is the coloured attractive inner floral envelope; usually the most conspicuous whorl. As a rule the petals are highly coloured, the colouring matter being contained in the cell-sap (blue and red flowers) or in *plastids* (*chromoplasts*) as in yellow flowers, or in both (orange flowers). Petals are generally glabrous, but in some instances hairs are produced. They often close the way to the honey-secreting part of the flower to small insects whose visits would be useless for pollination. Coloured hairs occur on the perianth of *Iris*. Normally thin and delicate petals occasionally become thick and fleshy (*Rafflesia*), dry (heaths), or hard and stiff (*Xylopia*). Each petal often consists of two parts, a lower narrow *unguis* or *claw*, and an upper, broad *lamina* or *limb* (fig. 38). The claw is often wanting (fig. 39) and the petals are then *sessile*. The limb may be flat, concave or hollowed. In hellebore the petals become tubular (fig. 40); in aconite (fig. 42), some resemble a hollow-curved horn, supported on a grooved stalk; while in columbine and violet (fig. 41) one or all are prolonged as a spur. In *Antirrhinum*, the spur is short and the petal is *gibbous* or *saccate*. These spurs, tubes and sacs serve as receptacles for nectar.

A corolla is *diptetalous*, *tripetalous*, etc., according as it has two, three, etc., separate petals; the general name *polypetalous* is given to corollas with separate petals, while those in which the petals are united are *monopetalous*, *gamopetalous* or *sympetalous*. This union generally takes place at the base and extends towards the apex. In the vine, the petals are separate at the base, adherent at the apex. In a sympetalous corolla the lower portion usually forms a tube, the upper parts a common limb, the point of union being the *throat*. The number of parts is determined by the divisions (teeth, fissures, etc.), or when, as rarely, the corolla is entire, by the venation. The union may be equal, or some parts may unite more than others.

Amongst regular polypetalous corollas may be noticed the *rosaceous* corolla; the *caryophyllaceous* corolla, in which there are five clawed petals; the *cruciform*, having four petals in the form of a cross, as in the wallflower. Of irregular polypetalous corollas, the most marked is the *papilionaceous* (fig. 28-29), in which there are five petals—one superior next to the axis, usually larger than the rest; and the *vexillum* or *standards*, two lateral, the *alae* or wings; two inferior, often united slightly to form a single keel or carina, which embraces the essential organs.

Regular sympetalous corollas may be *campanulate* or *bell-shaped* (*Campanula*); *hypocrateriform* or *salver-shaped* (*Primula*, fig. 43) *tubular* (comfrey); *rotate* or *wheel-shaped* (forget-me-not); *urceolate* or *urn-shaped* (bell-heath). Some of these forms may become irregular in consequence of certain parts being more developed than others; thus in the foxglove there is a slightly irregular campanulate corolla. Other irregular sympetalous corollas include the *labiate* or *lipped*, having two divisions of the limb, the upper usually of two, the lower of three, united petals, separated by a gap. When the upper lip is much arched, and the gap is distinct, the corolla is *ringent*; when the gap is reduced

33. Imbricated aestivation; 34. Vexillary aestivation; 35. Groundsel fruit with pappus; 36. Poppy calyx; 37. Fruit of *Physalis Alkekengi*; 38. Unguiculate petal of Wallflower; 39. Crowfoot petal; 40. Hellebore petal; 41. Pansy; 42. Part of Aconite flower; 43. Primrose flower; 44. Dandelion flower; 45. Stamens of Garden Pea; 46. Anther of Rush; 47. *Salvia officinalis* anther; 48. Nightshade stamen; 49. Barberry stamen; 50. Flower of Wallflower; 51. Pollinia; 52. *Asclepias* pistil; 53. Broom pistil; 54. Five-carpellary ovary; 63. Melon fruit; 64. *Cerastium hirsutum* pistil; 65. Same cut horizontally; 66. Carpel of Lady's mantle; 67. Primrose pistil; 68. Grass flower with glumes removed; 69. *Polygonum Convolvulus* ovary; 70. Gynaecium and stamen of Poppy; 71. Ovules; 72. Ovules; 73. Ovule

to a chink, as in snapdragon, *personate*. In *Calceolaria* the lips become much hollowed out. When a tubular corolla is split to form a strap-like process on one side, it is *ligulate* or *strap shaped* (fig. 44), as in many Compositae.

Petals are sometimes suppressed and at times the whole corolla is absent. In *Amorpha* there is only a single petal. In the Ranunculaceae some genera (e.g., *Ranunculus*) have both calyx and corolla, while others (e.g., *Anemone*) have only a coloured calyx.

The term *nectary* includes those parts of a flower which secrete a honey-like substance, as the glandular depression on the petal of *Ranunculus* (fig. 39). The honey attracts insects, which convey pollen to the stigma. The horn-like nectaries under the galeate sepal of *Aconitum* (fig. 42) are modified petals, as are the tubular nectaries of hellebore (fig. 54).

Petals are attached to the axis usually by a narrow base. When this attachment is by an articulation, the petals fall off either immediately after expansion (*caducous*) or after fertilisation (*deciduous*). A corolla continuous with axis, as in *Campanula*, may remain in a withered state while the fruit is ripening. A sympetalous corolla falls off in one piece.

ESSENTIAL ORGANS

As a stamen represents a leaf developed to bear pollen or microspores, it is spoken of in comparative morphology as a microsporophyll; similarly the carpels which make up the pistil are the megasporophylls (see ANGIOSPERMS). In plants with hermaphrodite flowers, self-fertilisation is often provided against by the structure of the parts or by the period of ripening of the organs. For instance, in *Primula* (fig. 43), some flowers (thrum-eyed) have long stamens and a short styled pistil, others (pin-eyed) short stamens and a long-styled pistil; these are *dimorphic*. In some plants the stamens are perfected before the pistil (*protandrous*); more rarely, the pistil is perfected first (*protogynous*). Plants in which protandry or protogyny occur are *dichogamous*. When the same plant bears unisexual flowers of both sexes it is *monoecious* (hazel); when the male and female flowers are on separate plants, the plant is *dioecious* (hemp); when there are male, female and hermaphrodite flowers, it is *polygamous*.

Stamens.—The stamens arise from the receptacle within the petals, with which they generally alternate, forming one or more whorls, collectively constituting the androecium. Their normal position is below the pistil (*inferior*), but they may be above (*superior*) or, as in Saxifragaceae, *half inferior* or *half superior*. Sometimes they adhere to the petals (*epitalous*), or to the pistil, so as to form a column (*gynandrous*). These arrangements are important in classification. Stamens vary in number from one to many, even hundreds. In acyclic flowers there is often a gradual transition from petals to stamens, as in the white water lily (fig. 21). When there is only one whorl the stamens are usually equal in number to the sepals or petals. The additional rows of stamens may be developed in centripetal order or interposed between the pre-existing ones or placed outside them, i.e., be developed centrifugally (geranium). When the stamens are fewer than 20, they are *definite*; when more, *indefinite*, represented by the symbol ∞ . A flower with one stamen is *monandrous*, with two, *diandrous*, with many, *polyandrous*, etc.

The function of the stamen is the development and distribution of the pollen, which is contained in the anther. If the latter is absent, the stamen cannot perform its functions. The anther is developed before the filament, which may be absent (e.g., mistletoe), when the anther is *sessile*.

The Filament.—The filament is usually thread-like and cylindrical, or slightly tapering towards its summit. It may, however, be thickened and flattened in various ways. The length sometimes bears a relation to that of the pistil, and to the position of the flower. Though usually of sufficient solidarity to support the anther in an erect position, the filament is sometimes (e.g., grasses) delicate and hair-like, so that the anther is pendulous (fig. 68). It is generally continuous, but sometimes is bent or jointed (*geniculate*), or spiral (e.g., pellitory). In *Fuchsia* it is red, in *Adonia*, blue; in *Ranunculus acris*, yellow. The filament

is usually articulated to the receptacle and the stamen falls off after fertilisation, but in *Campanula*, the stamens remain in a withered state. The filaments may cohere to a greater or lesser extent, the anthers remaining free. Thus, all the filaments may unite to form a tube round the pistil (e.g., mallow), the stamens being *monadelphous*, or they may be arranged in two bundles (*diadelphous*), as in the pea, where nine out of ten unite, the posterior one being free (fig. 45). In this case the stamens, originally free, cohere, but in most cases each bundle arises from the branching of a single stamen.

The Anther.—The anther consists of lobes containing the minute pollen grains, which, when mature, are discharged by an opening. There is a double covering to the anther—the outer *exothecium* resembling the epidermis and often bearing stomata; the inner *endothecium* formed by a layer or layers of cellular tissue, the cells of which have thickened walls. The endothecium generally becomes thinner towards the part where the anther opens out, and there disappears. The anther appears first as a simple papilla of meristem, upon which indications of two lobes soon appear. Upon these projections rudiments of the pollen-sacs, usually four, two on each lobe, are seen. In each differentiation takes place in the layers beneath the epidermis, by which an outer small-celled layer surrounds an inner one of larger cells. These central cells are the pollen mother-cells, the outer cells forming the endothecium while the exothecium arises from the epidermis.

When all four pollen-sacs remain permanently the anther is *quadrilocular* (fig. 46). Sometimes, however, the sacs in each lobe unite to give a *bilocular* anther. Further fusion of the lobes or the abortion of one of them (e.g., hollyhock) leads to a *unilocular* anther. Occasionally there are numerous cavities in the anther (e.g., mistletoe). The lobes are generally more or less oval or elliptical. The division between them is marked on the face of the anther by a *furrow*, and there is usually a suture indicating the line of dehiscence. Stamens may cohere by their anthers becoming *syngenesious* (e.g., Compositae).

The Connective.—The anther-lobes are united by the *connective* which is either continuous with the filament or articulated with it. When the filament is continuous and prolonged so that the lobes appear to be united throughout their length, the anther is *adnate* or *adherent*. When the filament ends at the base of the anther, the latter is *innate* or *erect*. In these cases the anther is fixed. When, however, the attachment is narrow and an articulation exists, the anthers are movable (*versatile*) as in grasses (fig. 68). The connective is sometimes extended backwards and downwards (e.g., violet) to form a nectar-secreting spur.

Anther Dehiscence.—The opening or dehiscence of the anthers to discharge their content takes place by clefts, valves or pores. When the anther-lobes are erect, the cleft is likewise along the line of suture—*longitudinal dehiscence* (fig. 16). In other instances the opening is confined to the base or apex, each locus opening by a single pore (e.g., *Solanum*, fig. 48); in the mistletoe there are numerous pores. In the barberry (fig. 49) each lobe opens by a valve on the outer side of the suture (*valvular*). Anthers dehiscence at different periods during the process of flowering, sometimes in the bud but more commonly when the flower is expanded. They may dehiscence simultaneously or in succession. These variations are connected with the arrangements for the transference of pollen. *Introrse* anthers dehiscence by the surface next the centre of the flower, *extrorse* anthers by the outer surface; when by the sides (e.g., *Iris*) they are *laterally* dehiscence.

Stamens occasionally become sterile by non-development of the anthers and are then called *staminodes*. Some stamens are enclosed within the tube of the flower (*included*) others are *exserted*, i.e., extend beyond the flower (e.g., *Plantago*); sometimes they are exserted in early growth, but become included later (e.g., *Geranium striatum*). When there is more than one whorl, the stamens on the outside are often longest (e.g., many Rosaceae), but sometimes the reverse is the case. When the stamens are in two rows, those opposite the petals are usually the shorter. In some flowers the stamens are *didynamous*, only four out of five

being developed and the upper pair longer than the lateral (e.g., Labiatae, Scrophulariaceae). When there are six stamens, four may be long and two short (*tetradynamous*), alternating with the pairs of long ones (e.g., Cruciferae, fig. 50).

Pollen.—The pollen-grains consist of small cells, developed from the large, thick-walled mother-cells in the interior of the pollen-sacs. A division takes place to form four cells in each mother-cell and these are the pollen grains, which increase in size and acquire a cell-wall, differentiated into an outer cuticular *extine* and an inner *intine*. Then the walls of the mother-cells are absorbed and the grains float freely in the fluid of the pollen-sacs. The fluid gradually disappears and the mature grains form a powdery mass. In most Orchidaceae the pollen-grains are united into masses (pollinia, figs. 51, 52) by viscid matter. Each of these has a stalk (*caudicle*) which adheres to a prolongation at the base of the anther (*rostellum*) by a viscid gland (*retinaculum*). *Gynandrium* is sometimes applied to the part of the column in orchids where the stamens are situated. The number of pollinia varies.

The extine is a firm membrane which defines the contour of the pollen-grain and gives it colour (generally yellow). The extine is either smooth or covered with projections and is often covered with viscid or oily matter. The intine is uniform, thin, transparent and extensible. In some aquatics (e.g., *Zostera*) only one covering exists.

Pollen-grains vary in diameter from $\frac{1}{300}$ to $\frac{1}{700}$ in. or less. They are most commonly ellipsoidal, but may be spherical, cylindrical and curved, polyhedral (Compositae) or nearly triangular in section. There are rounded pores varying from one to fifty, and through one or more of these the pollen-tube is extruded in germination. In monocotyledons there is usually only one, in dicotyledons, where they may form a circle round the equatorial surface, they number from three upwards. Within the pollen-grain is granular protoplasm with oily particles and occasionally starch. Before leaving the pollen-sac, the grain divides into a vegetative cell or cells, from which the pollen-tube arises, and a generative cell, forming the male cells (see ANGIOSPERMS, GYM-NOSPERMS).

Pollination.—When the pollen-sacs are ripe, the anther dehisces and the pollen is shed. In order that fertilization may be effected, the pollen must be conveyed to the stigma of the pistil. This *pollination* (q.v.) is promoted in various ways, the whole form and structure of the flower being adapted to the process. In some plants (e.g., pellitory) the mere elasticity of the filament is sufficient; in others (*anemophilous*) pollination is effected by the wind (e.g., grasses) and in such cases enormous quantities of pollen are produced; but the common agents of pollination are insects. To attract them to the flower the odoriferous secretions and gay colours are produced, and the position and complicated structure of the parts of the flower are adapted to the perfect performance of the process. It is comparatively rare in hermaphrodite flowers for self-fertilization to occur and the various forms of dichogamy, dimorphism and trimorphism prevent this.

Disk.—Under the term disk is included every structure intervening between the stamens and the pistil. It presents great varieties of form, such as a ring, scales, glands, hairs, petaloid appendages, etc., and often contains nectar. The disk frequently arises by degeneration or transformation of the staminal row. In cruciferae, it consists of tooth-like scales at the base of the stamens. The enlarged receptacle covering the ovary in *Nymphaea* may be regarded as a disk.

The Pistil.—The pistil or gynoecium occupies the centre or apex of the flower and is surrounded by the stamens and floral envelopes when these are present. It constitutes the innermost whorl, which after flowering is changed into the fruit and contains the seeds. The ovary contains the ovules attached to the *placenta*. The pistil consists of one or more modified leaves, the *carpels* (megasporophylls). When a pistil consists of a single carpel, it is *simple* or *monocarpellary* (fig. 53); when composed of several carpels, it is *compound* or *polycarpellary* (fig. 54). Each carpel has its own ovary, style (when present) and stigma and may be regarded as formed by a folded leaf, the upper

surface of which is turned inwards, towards the axis; the lower outwards, while the ovules develop from the margins. A pistil is usually formed by more than one carpel. These may be arranged at the same height in a whorl, or at different heights in a spiral. When they remain separate and distinct (e.g., hellebore, fig. 54) the pistil is *apocarpous*; when they unite (e.g., pear) it is *syncarpous*. A flower with a simple pistil is *monogynous*; with two carpels, *digynous*, with three, *trigynous*, etc.

The union in a syncarpous pistil is not always complete; it may take place by the ovaries alone (fig. 58), when the organ becomes a compound ovary; or by ovaries and styles; or by stigmas and the summits of these styles. Various intermediate states exist; the union is usually most complete at the base.

The Placenta.—The ovules are attached to the placenta, through which the fibrovascular bundles pass. The placenta is usually formed on the edges of the carpellary leaf (*marginal placentation*). But often the placentas arise from the axis (*axile placentation*) and are not connected with the carpellary leaves. In marginal placentation, the placenta is borne on the *inner* or *ventral suture*, corresponding to the margin of the carpellary leaf, the *outer* or *dorsal suture* corresponding to the mid-rib. As the placenta is formed on each margin of the carpel, it is essentially double. When the pistil is simple, the inner margins unite and usually form a common placenta. When the pistil is apocarpous, there are generally separate placentas at each margin. In a syncarpous pistil, however, the carpels are so united that the edges of each of the contiguous ones, by their union, form a *septum* or *dissepiment*, and the number of these septa consequently indicates the number of carpels in the pistil. When the septa extend to the axis, the ovary is divided into cells, being *bilocular*, *trilocular*, etc., according to the number, each cell corresponding to a single carpel. In these cases, the marginal placentas meet in the axis and unite to form a single *central* one. When the carpels of a syncarpous pistil do not fold inwards, the ovary is *unilocular* and the placentas are *parietal* (e.g., *Viola*). Often the margins of the carpels which fold in to the centre split there into two lamellae, each of which is curved outwards and projects into the locument, dilating at the end into a placenta (e.g., Cucurbitaceae, fig. 63). Cases occur, however, in which the placentas are not connected with the walls of the ovary (*free central placentation*, figs. 64, 65); this may be due to the separation of the carpellary leaves from the axis, as in Caryophyllaceae, in which there are often traces of the septa at the base of the ovary; or to the placenta being an axile formation produced by the elongation of the axis (e.g., Primulaceae).

Occasionally divisions take place in ovaries which are not formed by the edges of contiguous carpels. These *spurious dissepiments* are often horizontal, only developed after fertilization. In Cruciferae, however, they are vertical and arise from the prolongation of the placentas.

The ovary is usually spherical or curved, sometimes smooth on its surface, at other times hairy and grooved. The grooves usually indicate the divisions between the carpels. When the ovary is on the centre of the receptacle, free from the outer whorls, so that its base is above the insertion of the stamens, it is *superior* (e.g., *Primula*, figs. 43, 67). When the margin of the receptacle is prolonged upwards, carrying with it the floral envelopes and staminal leaves, the basal portion of the ovary being formed by the receptacle and the carpellary leaves alone closing the apex, the ovary is *inferior* (e.g., *Fuchsia*). In many Saxifragaceae these are intermediate forms (*half-inferior*).

The Style.—The style proceeds from the summit of the carpel (fig. 67) and is traversed by a narrow canal, a continuation of the placenta, constituting conducting tissue, which ends in the stigma. In some cases, owing to more rapid growth of the dorsal side of the ovary, the style becomes lateral (fig. 66); this may be accentuated so that the style appears to arise from the base (*basilar*); but it still indicates the organic though not the apparent, apex of the ovary. Several basilar styles may unite (e.g., Boraginaceae) to form a single *gynobasic* style. The style is usually cylindrical, filiform and simple; sometimes it is grooved on one side, or flat, thick, angular, compressed or even petaloid

PAINTED FOR THE ENCYCLOPÆDIA BRITANNICA BY HELEN DAMROSCH TEE-VAN

NORTH AMERICAN WILD FLOWERS

Some 12,000 kinds of flowering plants grow wild in the United States and Canada, many of which are noted for their handsome flowers. Conspicuous groups are the asters, golden rods, lilies, phloxes, columbines and gentians, found across the continent; mag-

nollas and azaleas especially in the South; trilliums and violets in the East; and lupines and poppies in the West. See articles on the different flowers. (St. fl. is placed after such flowers as have been adopted as State flowers.)

1. Orange Lily (*Lilium canadense*). 2. Summer Phlox (*Phlox paniculata*). 3. Golden Rod (*Solidago canadensis*), St. fl., Ala., Nebr. 4. Bluebonnet (*Lupinus texensis*), St. fl., Texas. 5. Cardinal Flower (*Lobelia cardinalis*). 6.

- Blue Columbine (*Aquilegia caerulea*), St. fl., Colo. 7. New England Aster (*Aster novae-angliae*). 8. Moccasin Flower (*Cypripedium acaule*), St. fl., Minn. 9. California poppy

- (*Eschscholtzia californica*), St. fl., Calif. 10. Fringed Gentian (*Gentiana crinita*). 11. Magnolia (*Magnolia grandiflora*), St. fl., La. and Miss. 12. Trailing Arbutus (*Epigaea repens*), St. fl., Mass.

(e.g. *Iris*). It may bear hairs, which aid in the application of pollen to the stigma (collecting hairs, e.g. *Campanula*). The styles of a syncarpous pistil, when separate, alternate with the septa; when united, the style is *simple* (fig. 67). The style of a single carpel may be divided. The length of the style depends upon the relation which should subsist between the position of the stigma and that of the anthers to allow proper application of pollen.

The Stigma.—The stigma is the termination of the conducting tissue of the style and is usually in direct communication with the placenta. It consists of loose cellular tissue and secretes a viscid matter which detains the pollen and causes it to germinate. The stigmas alternate with the septa of a syncarpous pistil, i.e. corresponds to the back of the loculi; but in some cases half the stigma of one carpel unites with half that of the next, the stigmas being thus opposite the septa (e.g. poppy). The divisions of the stigma usually mark the number of carpels in the pistil, but sometimes (e.g. Gramineae) the stigma of a single carpel divides. It may be terminal or lateral and may present sensitive laminae which close when touched (e.g. *Mimulus*). It may be globular, umbrella-like, ovoid (e.g. *Fuchsia*), radiating, as in the poppy, where the true stigmatic rays are attached to a shield-like (*pel-tate*) body. The lobes of the stigma may be flat and pointed, fleshy and blunt, smooth, granular or feathery (e.g. many grasses, fig. 68). In Orchidaceae, the stigma is on the anterior surface of the column beneath the anthers.

The Ovule.—The ovule is usually produced on the margin of the carpellary leaf, but sometimes ovules arise all over the surface of the leaf, or from the floral axis, terminally (e.g. Polygonaceae) or laterally (e.g. Primulaceae). The ovule is usually contained in an ovary and is *angiospermous*; but in the Coniferae and Cycadaceae it has no proper ovarian covering and is *naked* or *gymnospermous*. It is attached to the placenta either directly (*sessile*) or by a *funicle* (figs. 71, 72, 73); this cord may become much elongated after fertilization. The ovule is attached to the placenta or funicle by its *base* or *hilum*, the opposite end being its *apex*.

The ovule first appears as a small projection from the placenta. The cells multiply and assume an enlarged ovate form constituting the *nucellus*. This nucellus may remain naked and alone form the ovule, as in some parasitic families; but in most plants it becomes surrounded by integuments, which appear first as rings at the base of the nucellus, which gradually spread over its surface. In some cases (e.g., Compositae), only one covering is formed, but usually another is developed subsequently, covering the first completely except at the apex, where neither integument invests the nucellus, but leaves an opening, the *micropyle*. A single cell of the nucellus enlarges to form the *embryo-sac* or *megaspore*, which gradually supplants the tissue of the nucellus until only a thin layer is left, and at the apex it may extend beyond it, or pass into the micropyle. In gymnosperms it usually remains deep in the nucellus. For further development, see ANGIOSPERMS, GYM-NOSPERMS.

The point where the integuments are united to the base of the nucellus is the *chalaza*, which is often coloured, is denser than the surrounding tissue and is traversed by vascular bundles from the placenta. When the chalaza is at the hilum and the micropyle is opposite, there being a short funicle, the ovum is *orthotropous* (fig. 72). When by more rapid growth on one side than on the other, the nucellus and integuments are curved on themselves so that the micropyle approaches the hilum, the ovule is *campylotropous* (e.g., Cruciferae, fig. 71). In an *inverted* or *anatropous* ovule (fig. 73) the commonest form in angiosperms, the apex with the micropyle is turned towards the point of attachment of the funicle to the placenta and the funicle coalesces with the ovule to form the *raphe*. The ovule thus curves from the point of origin of the integuments and if a second integument is formed, it does not extend to the side adherent to the raphe. Forms intermediate between these types occur. When there is a single ovule with its axis vertical, it may be attached to the placenta at the base of the ovary (*basal placenta*), when it is erect (e.g., Compositae); or it may be inserted a little above the base on a parietal placenta

(ascending); or it may hang from an apical placenta at the summit of the ovary, its apex being directed downwards (*inverted* or *pendulous*); or from a parietal placenta near the summit (*sus-pended*, e.g., Euphorbiaceae). Sometimes a long funicle arises from a basal placenta, reaches the summit of the ovary and there, bending over, suspends the ovule (e.g., sea-pink); at other times the hilum appears to be in the middle and the ovule is *horizontal*. When there are two ovules in the same cell they may be side by side (*collateral*); or one erect and the other inverted; or one above the other, as is the case in ovaries containing a moderate number of ovules. When the ovules are *definite* (i.e., uniform and can be counted) their attachment usually forms a good character for classification. When very numerous (indefinite) and the placenta little developed, their position shows great variation and their form is altered by pressure into various polyhedral shapes.

Fertilization.—When the pistil has reached a certain stage in growth, it becomes ready for fertilization. The pollen-grain having reached the stigma in angiosperms, or the summit of the nucellus in gymnosperms, it is detained there, and the viscid secretion from the glands of the stigma or from the nucellus induce the protrusion of a pollen-tube through the pores of the grain. The pollen-tube (or tubes) passes down the canal (fig. 69), through the conducting tissue of the style, when present, and thence to the micropyle of the ovule, one pollen-tube going to each ovule. Frequently the tube has to pass some distance into the ovary, to reach the micropyle, being guided by hairs, grooves, etc. In gymnosperms the pollen-grain resting on the apex of the nucellus sends off its pollen-tubes which at once penetrate the nucellus (fig. 69). Ultimately the apex of the tube perforates the tip of the embryo-sac, the male cells are transmitted to the sac and fertilization is effected. Consequent upon this, after a longer or shorter period, those changes begin in the embryo-sac which result in the formation of the embryo plant, the ovule being converted into the seed, the ovary enlarging to form the fruit, often incorporated with which are other parts of the flower (receptacle, calyx, etc.). In gymnosperms the pollen-tubes, having penetrated a certain distance down the tissue of the nucellus, are arrested in growth for a period, sometimes nearly a year. See ANGIOSPERMS: Flower; FRUIT; SEED.

FLOWER ARRANGING in Japan is an old art of composing natural flowers, foliage or fruit-bearing branches in a vessel for the decoration of a room. Its important position in the home was established in the middle of the 15th century, when the tea-ceremony (*q.v.*) became a fashion, and so popular did it grow that it soon became independent of the tea-room to be taught by flower-masters. By the 17th century there arose many schools or styles which held competitive exhibitions of their art. Such exhibitions are still being held and there are more than 100 styles, the number still increasing. Private lessons are given by numerous flower-masters and a course on flower arranging, or to use the Japanese term, *ikebana*, is included in the curriculum of nearly all the girls' schools in Japan.

Common to practically all the styles is the principle guiding the fundamentals. There is to be a tall spray representing the "leading principle," Heaven. Another branch should be kept low down to denote the "subordinate principle," Earth. And there is to be another branch between the two which stands for the "reconciling principle," Man. Thus an effort is made, besides aiming at a beautiful form, to indicate man's relation to the universe. There should always be these three prominent features, however many other branches of minor significance may be added, the joining of these principal points forming a triangle. However, the *rikka* (standing flowers), a special art of the Ikenobo school, may be considered an exception: it denotes the universe with actual suggestions of landscapes by the branches and flowers. In each style the highest artistic value of a vase of flowers is brought out in its relation to the season, the occasion, and the other objects of ornament, chief among which is the *kakemono*, the hanging picture. As the arranged flowers are to be placed on the *tokonoma* (an alcove in the guest room) they are so composed as to be best seen from the front. Now that there are so many foreign styled rooms in the Japanese houses, it has become neces-

sary to have flowers so arranged as to be appreciated from all sides, and there is a tendency to develop a style to meet this requirement.

BIBLIOGRAPHY.—J. Conder, *The Flowers of Japan and the Art of Japanese Floral Arrangement* (Tokyo, 1891); F. Brinkley, *Japan—Its History, Arts and Literature* vol. iii. (Boston and Tokyo, 1901); Mary Averill, *The Flower Art of Japan* (1926). (J. HAR.)

FLOWER FARMING. Flower growing for the wholesale market has become a great industry in many countries with the development of wealthy urban populations of cultured taste. England, the United States, France and Holland have important flower outputs.

Flower Farming in England.—In 1925 the Ministry of Agriculture estimated that the area devoted to flower production in England in the open fields was about 5,250 acres. Daffodils and narcissi accounted for about 1,400ac., tulips 300ac., violets 150ac., and other flowers 3,400 acres. The value of flowers grown in the open was estimated at about £400,000.

In addition, flowers are produced in glasshouses, the source of the very choicest and early forced blooms. Daffodils, tulips, iris, lilies, etc. are forced in advance of the outdoor crop, roses and carnations are kept cropping both winter and summer, while choice chrysanthemums are produced long after the outdoor varieties have been cut down by frost. The value of the glasshouse blooms far exceeds those from the fields. In 1925 the outputs of glasshouse grown chrysanthemums, roses and carnations were valued at £250,000, £250,000 and £85,000 respectively. Cut flowers and flowering plants in pots produced in glasshouses were valued at £1,350,000. Thus the output of flowers from open fields and from glasshouses was in all £1,750,000.

Flower Growing in France.—In various parts of France, and notably around Paris, there are glasshouses devoted to roses and cut flowers. Nevertheless the greater part of the industry is carried on in the open fields of the Riviera district. During rough or cold weather some kinds are protected with rush mats or glass lights, but in the main the French flower production is that of the open field. The flower area extends from Toulon beyond the border into the Italian Riviera. Toulon is important for narcissi, Hyères for violets, Cannes for mimosa, and Nice for carnations and roses. Ranunculus, anemones, alliums and Spanish iris are also grown.

Flower Growing in the Netherlands.—Flower culture in Holland is mainly devoted to the ends of the bulb industry. In the spring the fields of narcissi, daffodils, tulips and hyacinths give a blaze of colour not seen anywhere else in the world. These fields are the main source of the world's bulbs, and large quantities are exported annually to all parts. The area of cultivation is estimated to be about 15,000ac. and lies mainly between Amsterdam and Leyden; tulips predominate at Haarlem, hyacinths at Lisse and daffodils and narcissi at Sassenheim, though much general planting of all kinds occurs at each centre. Bulbs are also forced in glasshouses to produce cut flowers, and with the flowers gathered from the open fields the cut flower industry is considerable, large quantities, especially of tulips, being exported to England, Germany and France.

The American Flower Industry.—Floriculture has made great progress in the United States and to a lesser extent in Canada, and, beginning in the large centre round Boston, New York, Philadelphia, etc., has spread on some scale everywhere. American floriculture is carried on in specially built glasshouses, some of which are of a scale bigger than any yet built elsewhere. In 1900, the industry was said to occupy 9,307ac., in 1910 18,248ac., and in 1928 it is more than twice as large as in 1910. The principal flowers grown in their order of importance are roses, carnations, violets, chrysanthemums, sweet peas, lilies of the valley, bulb-flowers and orchids. Sweet peas are becoming very popular and in importance will soon rank before violets, if they have not yet done so. Whilst glasshouses of great size are built for mass production, good culture has not been sacrificed, and American roses are not surpassed elsewhere.

Spring Flowers.—While flowers such as mimosa, lilac, freezia, daffodils, narcissi, snowdrops, anemones, violets and iris come to

herald the spring, and are usually spoken of as spring flowers, even before Christmas European markets are supplied with violets and mimosa from the French Riviera and with the white narcissi (Paper white or Mediterranean white) from Toulon. These are followed early in January by daffodils and narcissi from the Scilly isles. By Easter time supplies are general in all countries. The Scilly isles function as a spring flower garden for Great Britain. The flowers are grown mostly on the islands of St. Mary's and Tresco. Pickings commence in the open fields with daffodils (Henry Irving, Emperor, Golden Spur), and with narcissi (Soleil d'or) soon after Christmas. For the first bunches prices rule high, but quickly fall as the daily supplies increase.

All these spring flowers are also grown in England near Penzance, in Middlesex and in Lincolnshire. The Lincolnshire area which is situated around Spalding follows closely the Dutch methods of culture, emigrants from the Netherlands having settled in Lincolnshire and done much to stimulate flower farming there. Here also are grown in the open fields the vast majority of tulips produced in England.

Forcing Bulbs into Flower.—Forcing is done in the Scilly isles, Cornwall, Lincolnshire and Guernsey; the largest forcers are centred about Uxbridge, Cheshunt, Hampton and other districts near London. When bulbs have grown in the open field to a large size they are suitable for forcing, and large quantities of these "forcers" are sold each autumn. Golden Spur, Emperor, Empress, Ornatus and Horace are popular daffodils for this purpose. Of tulips a good many varieties are used, Duc van Hols, Diana, King of the Yellows, for Christmas flowers; Salvator Rosa, Thomas Moore, Prince of Austria and Ionricesall Flamingo, Wm. Pitt and Wm. Copeland for January use; and Franz Hals, King Harold, Himese for February.

Forcing tulips requires much care; the bulbs must be in the boxes by August or early September, the soil must be light virgin loam containing much bone meal. The boxes covered with earth should stand in a cool and shady spot for a time for root development, before being taken to forcing rooms maintained at 60° F.

Violets.—The violets of the florist's shop are the product of special culture in selected places; one very suitable spot is the French Riviera, especially in the region of Hyères, in which region very large quantities are produced every winter. In England violets are grown in open field culture in the Scilly isles, Cornwall, Devon, Dorset, Hants, Sussex and Kent. Violets grow exceedingly well in the south-west of Ireland, where in county Cork important commercial violet farms exist. In America violets are grown in specially constructed glasshouses.

The violet is a sensitive plant, very exacting in its requirements. It needs much sunshine but will not tolerate heat or dryness; it must be sheltered from winds and in some instances protected from frost. Clay lands are too cold and wet, whilst sandy soils become too hot and dry.

There are a large number of varieties in cultivation, but nearly 90% of the shop blooms are of the variety Princess of Wales, which yields best under commercial conditions. The plants of this variety should commence flowering in October and continue to give crops till March; Baroness Rothschild and California are blue of a similar type with long stems. Double violets are grown in smaller quantities, the best being Marie Louise (mauve) and Comte de Brazza (double white). These are the "Parma" violets of the shops.

In open field culture the plants are grown in beds 9ft. wide to take 10 plants 12in. apart with 14in. between the rows, thus giving about 30,000 plants to the acre. An acre of good plants should produce not less than 45,000 bunches and the selling price varies from 2s.6d. per dozen bunches in the early part of the season to 9d. per dozen later when blooms are plentiful.

Sweet Peas.—These lovely flowers are much grown. In districts which are favourable, sowing should begin during the autumn on well cultivated land richly manured with rotten dung. The seeds must be sown very thinly, so that the plants are at least 3in. apart. In districts where autumn sowing is not safe, the seeds should be sown during October in small pots—two or three seeds in size 60 pots—and these should be kept in a house or frame

JAPANESE STYLES OF FLOWER ARRANGING

1. Flowers arranged in Seizan-Ryu style. The Seizan-Ryu school is an outgrowth of the Ikenobō cult (see figs. 4 and 5)
2. Flowers arranged in Tozanko-Seiryu style (see figs. 7 and 8). The triangular grouping, characteristic of all Japanese flower-arrangement, symbolizes Heaven, Earth and Man
3. Another arrangement of flowers in Seizan-Ryu style (see fig. 1)
4. Pine, plum and bamboo arranged for a happy occasion, in Ikenobō style
5. Autumnal flowers arranged in Ikenobō style, in combination with a kakemono (hanging picture), suggesting the singing of autumn insects
6. Arrangement in Mori-bana style
- 7 and 8. Further examples of Tozanko-Seiryu style (see fig. 2). The grouping with all the stems together at the base is typically Japanese
9. Lotus arranged according to Soami style. Soami (15th century) is reputed to have been the originator of the three-element style
10. Rikka, or standing flowers, grouped to suggest a landscape, a style peculiar to the Ikenobō school
11. Flowers arranged in Tensho-Koryu style. As in all Japanese arrangements, an effect of even symmetry is avoided
12. Flower arrangement according to Shogetsudo-Koryu style, originated by Myōye-Shōnin in 1171-1231

free from frost during the winter, though no forcing must be attempted. If little heat is used and the plants are given plenty of ventilation, good sturdy plants should be ready by April, when they may be planted out during good weather to bloom in June.

Sweet peas also are grown under glass for early blooms, and these crops yield the choicest blooms. The seeds are autumn grown in pots and planted out about March into beds specially prepared in the houses and kept growing, so that by April they are two to three feet high. All tendrils and side growths are removed and the plant kept upright by being twisted around string hung from the roof. Ventilation must be given at all times, and plenty of tepid water. In May, when the flower spikes are showing, feeding with liquid manure may commence.

The English sweet pea industry is expanding, but is still very much smaller than that of the United States, where sweet peas are grown in immense quantities.

Carnations.—The area of carnation houses has greatly increased; supplies of the flowers have more than trebled in recent years; yet there seems to be a market for all and especially for the best grown blooms. Formerly glasshouses of small size were used, but some of the new houses are 100yd. long and hold as many as 15,000 plants.

The carnation plants are grown in prepared beds of soil, a good loam enriched with well rotted manure and some bone meal, four to six inches deep, preferably raised to provide good drainage and aeration. Regular water and fortnightly feeding is necessary. A high temperature in the house is harmful; one of 46° F to 50° F during dry weather is sufficient for the growth, and this is best attained by running hot water pipes above the plants rather than low down as in tomato houses.

The following list gives a selection of the best varieties of each colour:—

Pink. Mayday, Mrs. Walter Hemis, Enchantress Supreme. *Salmon* Pink. Lady Northcliffe, Bona, Cupid, Laddie. *Scarlet.* Aviator, Tarzan, Beacon, Edward Alwood. *Crimson.* Triumph, Nigger. *White.* White Wonder, Wivelsfield White, White Mayday. *Cerise.* Peerless. *Mauve.* Mikado, Eastern Maid, Wivelsfield Claret. *Yellow.* Saffron, Sunshine.

Rose Culture Under Glass.—Rose culture under glass is essentially different from that of the open gardens, for by special pruning and manuring the indoor rose plant is made to give blooms almost continuously. Few varieties are grown, Richmond (red-scarlet), Ophelia (salmon), Madame Butterfly (salmon to rose), and Lady Hillingdon (orange yellow) being the chief kinds. Three-year bushes budded on manetti stock are planted in beds of loam, heavily manured with dung and fertilizers. The plants are kept cut hard back and the rich soil forces out new strong growths which develop blooms on the tips. If the bloom commences before the stem is of sufficient length, the bud must be picked out and the shoot allowed to make further growth before flowering, for long straight stems are essential. Roses are grown in this way in Holland, North America and England. The English roses are all needed at home. The Dutch roses are mainly exported to England and Germany. Rose growing under glass has attained its greatest measure of development in the United States; the plants seem to appreciate the bright American sunshine, for the roses are exceedingly fine and have very long stems.

Lily of the Valley.—There are now many thousands of acres of land in the United States, England, Holland and Germany devoted to the production, not of the flowers but of the crowns (roots) of this flower. In October these crowns are packed an inch apart into boxes with the crown flush with top and covered with any light sandy soil. The boxes are well watered and covered with moss or coconut fibre to a depth of three or four inches. When placed in houses heated to 80°–95° F growth soon commences, and when the shoots are two to three inches long the moss is removed and light gradually admitted. Heavy daily watering must be made until the blossoms appear. Boxes of crowns placed in refrigerated chambers having a temperature of 28° to 30° F remain dormant. These may be taken out at any required time and forced into flower in greenhouses.

Lilies.—In all countries the chief lily of the market gardener is the White Trumpet—(*Lilium longiflorum*)—the bulbs of which

are raised in Japan and Bermuda. By forcing some bulbs, growing others in natural heat, and retarding the growth of yet others by keeping the bulbs in refrigerated chambers, the grower produces these tall White Lilies at all seasons of the year, though the greatest demand comes at Easter and Christmas. Fine bulbs are put into a 6-in. pot provided with much drainage, and covered with good medium loamy soil, leaf mould or rotten manure. The flowers are cut with long stems in the bud stage, packed firmly in very long shallow boxes and despatched to the markets.

Lilium speciosum also is much used in making wreaths and bouquets. It is smaller and of a different shape. The colours vary from deep red and rose spots on white to white without spots. The culture is similar to that described for *longiflorum*.

Chrysanthemums.—Some few varieties of chrysanthemums flower very early and yield their market crop before the frost comes. Varieties which do this are grown out of doors in beds 12ft. by 4ft. 6in. in rows 18in. apart and with 18in. from plant to plant. The following are the most desirable kinds for growing:—Framfield Early Primrose (white); Holicot Yellow (yellow); Golden Almirante (orange yellow); Mrs. Jack Pearson, Bronze Goacher (bronze); Almirante (chestnut); Normandie (pink); Lighfield Purple (purple).

In indoor culture, cuttings are placed in pots in November; when rooted the plants should be potted on and receive no check from the commencement until they have flowered. The indoor plants need training, i.e., the stems are stopped by pinching out the tops, so that the plant "breaks" into fresh growths and the cultivator is able to flower as many of these as he desires. Those who aim at large choice blooms must thin off all except the terminal bud; energy is concentrated into a few stems and the flowers grow to a large size. Grown naturally, chrysanthemums would develop into a bush, producing flowers in sprays, and although "Spray Chrysanthemums" are sold in the market the price paid is often low. The greenhouse during the winter months should have just sufficient heat to keep out frost, but any attempt at forcing should be avoided for chrysanthemums do not respond well to such treatment. Periodic spraying with nicotine and soft soap (1 oz. nicotine, 1 lb. soft soap and 12gal. rain water) should be practised to kill aphids.

Holicot (yellow), Alcaldo (bronze) and Debutante (white) are early blooms, Norman (single yellow), Ada Brookes, Chieftains, Mary Morris, Mrs. N. C. Cotlow, Mrs. J. Bassell, Pioneer, Balcomb Beauty, K. C. Pulling and Majestic are popular varieties. Each grower has his own particular fancy, which matters little, for in the market the flowers are sold as whites, yellows, bronze, etc.

Flowering Plants in Pots.—At special seasons of the year flowering plants in pots are much in demand. At Christmas time, and in America also at Easter time, the flower markets and shops are full of flowering hyacinths in bowls and pots of azaleas, cyclamens, spireas, hydrangeas and heaths, which are readily sold at good prices.

The Belgian growers have specialized in azaleas, and their special culture in pots of small bushy plants full of flowers may be had about Christmas time. Large quantities are exported from Belgium during the autumn, and these are forced into bloom by Christmas. They need a good deal of water. After flowering, the plants should be pruned and allowed to make new growths which should be ripened off by standing the plants out of doors during July and August.

The market grower raises his cyclamen corms from seed. These are grown in shallow pans of leaf mould and sand in July or August. The seeds take some time to germinate and come up very irregularly. When large enough to handle, each seedling should be potted to rich loam and leaf mould and grown in houses at 60° F to 65° F. As the plants grow they are shifted into larger pots, finally being placed into those of size 48 in about 12 months' time from the date of sowing the seed. The plants may now receive bone meal, Guano liquid manure and then go into a house heated to about 50° F, where they develop their blooms. These pots of cyclamen in full bloom find a ready sale during December and January.

Popularity of Cut Flowers.—The public to-day appreciates flowers so much that those in the industry are surprised at the great expansion of the cut-flower trade. The volume of trade has grown enormously together with an increased variety of flowers. A grower may now send to market any kind of choice flowers and secure a sale. Dahlias, delphiniums, zinnias, gladioli, etc., are welcome and find buyers no less than the sorts which have been mentioned above. The public taste is for large well grown blooms of bright colours, sweet scented, if possible; but there is little demand for poorly grown specimens, and indifferently developed blooms are almost unsaleable. Flower growing, to be successful, must be the work of a specialist. (H. V. T.)

United States.—So far as flowers are concerned there appears to be little difference between the kinds of plants grown in the United States, in England and on the Continent. Since the enforcement of Quarantine No. 37 which prohibits the introduction into the United States, except by special permit, of all plants with soil on the roots and certain bulbs, there has been less interchange of plants between Europe and America than in the earlier days. The United States is now dependent on its own nurserymen for its supply of azaleas, araucarias, bay trees and many other species formerly imported in large numbers from European countries. Greenhouse establishments in America are considerably more numerous than in England and variations in climatic conditions make it necessary to pay considerably more attention to heating problems. Steam is more generally used for heating than hot water.

Roses are without doubt the most important cut-flower crop produced in America. Extensive areas of glass are devoted exclusively to their culture in the eastern and central States. Within recent years there has been a decided change in the varieties grown. Bud variations and seedlings of American, German, French, Irish, Dutch and English varieties are widely grown; such varieties as Briarcliff, Mme. Butterfly, Rapture, Premier, Rose Hill, Mrs. F. R. Pierson and the offsprings of Souvenir de Claudius Pernet, Fontanelle, Gaiety and others, have replaced, in the American trade, Killarney, Ophelia and other European varieties. White Killarney, however, still continues as the best white rose in the American market. Carnations are now less generally grown in America and the large numbers of other species, such as calceolarias, snapdragons, lupines, delphiniums, stocks and many annual plants which are now being grown for winter cut-flowers under glass have taken the place of carnations to a considerable degree. Orchids are rapidly becoming an important commercial cut-flower crop. Among potted plants semi-tuberous begonias, cyclamen, primroses, cinerarias, calceolarias and many other species are grown. In America there is also a considerable trade in outdoor flowers such as sweet peas, asters, dahlias, gladioli and others. Many seedling palms are now being propagated and grown, especially in California, to supply the American trade.

FLOWERLESS PLANTS: see PTERIDOPHYTES, BRYOPHYTES, ALGAE, FUNGI.

FLOWER PAINTING. Broadly speaking, flower painting may be divided into two big classes: that of the East, and that of the West. In the East, flower painting very early attained to a high state and became an individual, extremely beautiful art in China between the 7th and 17th centuries. Japanese painters, adopting many of the traditions of Chinese art, created a phase of flower painting which rose to superb heights in the 16th and 17th centuries. In the West, flower painting proceeded slowly from Egyptian, Grecian and Roman days, on through the Italian Renaissance, until, mainly in the north of Europe, again in the 16th and 17th centuries, almost with one bound, it reached a distinctive and highly developed form of painting in the Netherlands, and from there spread to nearly every country of Europe. The two schools grew under conditions so separated that each remained until recent times quite untempered by the other.

Flower painting of modern times is something of a heritage of both these divisions, but mainly of the Western group, to which has been added a richer and fuller sense of colour, finer and more subtle effects of light and atmosphere resulting from the greater

development of visual perception and the delving into the realms of science, as developed by the French impressionists. The manner of painting flowers has followed the changes that have taken place in painting generally, whether of the East or of the West. In method, in the West, the early form was fresco, then oil; now water-colour and pastel are employed in addition. With the Chinese and Japanese, except in wall painting, it has always been a phase of water-colour painting, and their marvelous use of the brush on silk or paper has given a character found nowhere else in the world of art. In the Western world, flowers have been associated for the most part with man. They have appealed to his finer feelings; they have graced his life. He has used them as symbols, decorations, adornments, offerings and as enrichments to his home and his surroundings, while in the East they have always been thought of as a beautiful part of the great order of things in the universe, a part of nature of which man himself is likewise but a part. Flower painting, therefore, has developed along a far different line in the East from what it has in the West. In the East it has always been approached from a contemplative, philosophic and poetic point of view, while in the West it has been, for the most part from an objective one. In the West, we find flowers used in the early days only as accessories in the art of painting. At first they are painted as symbolical and decorative adjuncts. Later they assume a realistic phase in their conjunction with the religious and mythological subjects. But not until about the 16th century do they appear as subjects for paintings for their own beauty. In the East, however, they have formed a very distinct branch of painting for over a thousand years. The Chinese divided their paintings into four general subjects: landscape, man and objects, flowers and birds, plants and insects. Three of these main divisions deal directly in the broad field of nature; the third and fourth divisions are closely related, and being based on much the same conceptions as their landscape painting, follow it as a natural development.

THE ART IN CHINA AND JAPAN

The close observation and contemplation of nature by the artists of the East has produced in their work a rare character and charm. Their flower paintings vibrate with life and force; they are beautifully rhythmic. Their lilies nod and sway on delicate stems; lotus flowers vigorously grow from earth and water into light and sunshine. Their vines hang and sway in the breeze, their peonies unfold, their plum blossoms spread their petals and gently float away in the breeze almost as they open. Flowers in their paintings are associated with the passing of the seasons and the moods of nature. Generally they are painted with the birds of the seasons naturally associated with them at the time of flowering, in their natural habitat, and always with a great understanding of their life and growth. The Chinese artists ever communed with nature. It is said of Chao Ch'ang, of the early 11th century, that "every morning he would walk round the gardens and examine some flower carefully, turning it over and over in his hand. Then he would paint." Of I Yüan-chi, it is said that "he laid out a garden, planted it with bamboos and rushes, and kept there a variety of water fowl, so as to be able to watch them in movement and repose." Kuo Hsi writes about this same time: "Those who study flower painting take a single stalk and put it into a deep hole and then examine it from above, thus seeing it from all points of view. Those who study bamboo painting take a stalk of bamboo, and on a moonlight night project its shadow on to a piece of white silk on a wall."

Of the early Chinese flower paintings few remain to the present day, but of those known, the earliest are of the T'ang dynasty (A.D. 600-900) and show an art that must have been highly developed through many earlier centuries. Pien Luan, of the late 8th century, was noted for his paintings of birds and flowers. Hsiao Yüeh of the same century painted the bamboo exclusively. Hsü Hsi, of the early 10th century, was famous for his painting of flowers. "Peonies in the Wind" and "Ducks in a Lotus Pond" are typical titles. In his time he was considered an artist of the front rank, and has been called "the father of bird and flower painting." He was famous for his paintings of the lotus flowers

EUROPEAN FLOWER PAINTINGS

1. Vase of Flowers, by Jan van Huysum, Holland (1682-1749). 2. Roses aux Chèvrefeuilles, by Auguste Renoir, France (1836-94). 3. Vase de Fleurs, by Charles Dufresne, France. 4. Roses, by Henri Fantin-Latour, France (1836-1904). 5. Les Lauriers Roses, by Vincent van Gogh, Holland (1853-90)

FLOWER PAINTING

BY COURTESY OF THE TRUSTEES OF THE BRITISH MUSEUM

JAPANESE AND CHINESE FLOWER PAINTING

1. "Lotus, White Heron and Kingfishers" by an unknown Chinese painter of the Sung dynasty (960-1268), an example of the work of the period when flower painting advanced to a great art in China
2. "Chrysanthemums" by Tawarayo Sotatsu, an outstanding figure of the Tokugawa period in Japanese art. He worked between 1624-1643 and was the first to use gold as a pigment, mixing it with ink and colours

which were the inspiration for many painters in later times both in China and Japan. Huang Ch'üan and his son Huang Chü-ts'ai were noted painters of flowers of this same century. Two pictures, "Fowls" and "Peonies," in the British Museum are attributed to the father, while there is record of a large number of paintings of birds and flowers by the son.

The three centuries of the Sung dynasty (960-1260) saw flower painting advanced to a great art. It was a period of intense nature study, a period where a passion for flowers was common, a period when flowers were associated with nature and with every mood of nature. Many flower painters flourished, and their paintings are filled with an elusive poetic quality, combined with accurate form and rhythmic beauty of growth. In this phase of Chinese art, the Sung artists are pre-eminent. Hsü Ch'ung-ssü was a painter of flowers and insects, and is accredited with being the first to paint directly without first sketching the subject. Chao Ch'ang, who followed something of his methods, attained great fame. It is said of him that he "not only produces an accurate resemblance, but hands over to you the very soul of the flower" also. Ch'eng T'ang was famous for his paintings of bamboo, as was Chou Shun. Li-Ti excelled as a flower painter, Chao-Mêng-Chien delighted in painting the plum and narcissus, while Cheng Ssü-hisao devoted himself to the painting of orchids.

In the Yüan period, 1260-1368, there are few outstanding flower painters. Ch'ien Hsüan, born in the earlier dynasty, was noted, and Li K'an achieved great fame as a painter of the bamboo. In the Ming dynasty, 1368-1644, though a decline had set in, much of the tradition of the golden age of the Sung period was carried on, and a number of flower painters are found. Mr. Fenollosa claims for Lin Liang first place of all Ming artists. Lü Chi painted his flowers and birds with a landscape background. Sun K'an specialized in the painting of the chrysanthemum. Other flower painters of this time were Ch'ên Shun, Kao Ku, Sun K'o-hung, whose paintings were noted for beauty of movement in flowers, and Chou Chih-mien, also noted for the rhythm and spirit he attained. In the Ch'ing or Manchu dynasty, 17th to the 20th century, though no new vigour has been added, and marked signs of decadence are seen, many of the traditions in flower painting of the earlier Sung and Ming periods were maintained with vitality, at least to the beginning of the 18th century.

In Japan, flower painting, inspired greatly by the Chinese masters of the T'ang, Sung and Ming periods, possess many of their characteristics, grafted often on to the traditions of their own Japanese native schools of painting.

The most impressive periods were the Ashikaga period (1335-1573) and the Tokugawa, from about 1600 into the 19th century. The first strongly upheld traditions of the Sung painters. The native Japanese tradition slumbered, and a sort of Chinese renaissance in Japan took place. The gorgeous coloured scrolls, which had been typical, were replaced by bold simple ink paintings of birds and flowers and landscape. It was the philosophic, contemplative art of earlier Chinese painters. So far as flower painting was concerned, it was the interpretation of the life and growth of the flowers and their association with nature. Sesshiu and Kano Masanobu, the first of the great Kano school, both of whom had great influence and many followers, painted flowers in the classic Chinese style. Utanosuke, son of Kano Masanobu, achieved a great reputation for his distinguished painting of flowers and birds. He died in 1575. About 1600 began the Tokugawa period of Japanese art. Chinese ideals were developed along with the Japanese tradition for rich colour and sumptuous decorative effects. Artists with great skill and understanding vied with each other in producing a phase of flower painting, combining all the beauty of the growing flower with superb design and gorgeous colour, that remains unique in the entire field of painting. The three outstanding masters of flower painting of this period are Koyetsu (1557-1637), the leader in this movement, Sotatsu, considered by Japanese critics as the greatest of flower painters after Utanosuke, and Korin (1661-1716) who "is perhaps the most Japanese of all the artists of Japan." Their influence carried forward to recent times, but there are few, if any artists since who have inherited their skill or genius.

OCCIDENTAL FLOWER PAINTING

In the West, as has been said, the earliest painted flowers are only to be found as symbols or as decoration. The blue water-lily of the Nile, symbolizing a full harvest, is constantly found in the painted decoration of the Egyptians. Flowers repeatedly appear in the religious paintings of the Renaissance. The lily, emblem of purity, is painted in almost every picture of the Annunciation and of the Madonna. In Roman times garlands and festoons of flowers were painted as decorations. Fine examples, in excellent preservation, are those painted in fresco on the walls of the house of Livia on the Palatine. Crivelli and Mantegna continually in their pictures echo much of this festive decorative floral and fruit painting of the Romans. Flowers form a part in many of the pictures by Botticelli, and though generally introduced for their symbolism, or decoration, they show close observation of growing flowers and a delight in painting flowers for their own beauty, and are rapidly assuming an objective, or realistic character. They slightly suggest those found in some of the paintings of the late Ming period in China. Botticelli died in 1515, and this century witnessed an unprecedented interest in flowers and gardens. The Italians and Dutch both developed the making of gardens to a fine art. Merchants brought new and beautiful flowers from every corner of the earth to enrich them. In Holland this collecting of rare flowers became the fashion, and collectors of both Italy and Holland employed artists to paint them.

From 1550 to 1650 numerous painters in Italy, Spain and the Netherlands painted flower pictures for the beauty of the flowers themselves. Many of them attained great reputations, and a few were great masters. They exercised an influence that was immediately felt throughout Europe, and which has continued even to the present day. Jan Breughel (1568-1625) is generally acclaimed as one of the first to develop this manner of painting to a fine art, and, since he introduced flowers as decorative elements in religious painting something in the manner of the early painters of the Italian Renaissance, and later painted flower pictures, he may be considered as the most important link in the chain which leads to the highest point of flower painting in the West. Caravaggio (1569-1609), an Italian, as a young man made many paintings of flowers and fruit while in Rome. He did much to advance solidity and light and shade in painting, and his influence was felt both in Spanish and Dutch painting. From then on this feeling for light and shade and third-dimension was a markedly noticeable addition to painting. This phase, observed with greatest understanding, was almost scientifically accurate, and showed direct observation and study from nature. Daniel Seghers (1590-1661) painted in something of the same manner as Breughel, whose pupil he was. He, too, used flowers in conjunction with religious subjects, but they seem rather to be painted as offerings to the Madonna and saints than as garlands of enrichment. As paintings of flowers, they are very beautiful, with much of the charm of their form, looseness and grace of growth, and delicacy of texture. Individual flowers are masterpieces of close observation and painted with feeling for and knowledge of the flowers themselves.

The painting of garlands and festoons as accompanying decorations to other subject matter led in turn to separate flower paintings. Jan D. van Heem (1606-1684) developed this phase of flower painting to an amazing degree. His technique was masterly. His composition, colours, arrangements, lighting and feeling for the forms of flowers, which he generally painted against a simple dark background, produced a most finished and unified result. As an objective painter, he advanced flower painting to a point far in advance of what had gone before. He has seldom been surpassed. He achieved a great and deserved reputation, and is one of the real masters of this art. His influence was unmistakable, not only among the Dutch and Flemish painters, but throughout Europe. Almost simultaneously, we find groups of artists painting flower pictures in various countries, much in the manner of de Heem. In Italy, there were many, the most noted among which were: Giovanni Battista Ruoppoli (1600-59); Mario Nuzzi da Fiori (1603-73) (a pupil of Cavaliere Tommaso Salini's [1570-

1625], who was a contemporary of the Italian Caravaggio and the Flemish painter Jan Breughel, and who is claimed by Lanzi to have been "the first that composed vases and flowers accompanying them, with beautiful groups of foliage"; and the Roman, Michelangelo de Campidoglio (1610-70). In Spain, various members of the Arellano family painted in the van Heem and Caravaggio manner, the most famous being Juan de Arellano (1614-1672) whose flower paintings, generally painted in pairs, are greatly prized throughout Spain.

Later a German, Abraham Mignon (1639-1697), pupil of de Heem's, who worked in Holland, made for himself a reputation second only to his master. He, in addition to painting grouped flowers and fruit, painted growing flowers but with little of their rhythmic beauty of growth and no sense of their envelopment by air and light. Andrea Belvedere (1646-1732), a Neapolitan, is another painter, of this later time, with something of the Dutch tradition, much of Ruoppoli and something of Juan de Arellano's. Like him his flower paintings are often in pairs. His pictures are crowded but there is much, as in Arellano's, of the easy free growth of the flowers. The crowning point of this kind of flower painting was reached by Jan Van Huysum (1682-1749), who painted well into the 18th century. His flowers are masterly in the drawing of their exquisite and beautiful forms, superb in their third-dimensional quality, and in their delicate and gracious contours. His combinations of colour, his contrasting of light flowers against dark and his design of the wealth of blossoms portrayed, produced gorgeous decorative effects and place him without question as one of the greatest masters of flower painting. Yet his paintings lack a feeling for the living flower and do not possess that quality of growth so superbly grasped by the artists of the East. They lack, too, the beauty of transmitted light and translucent colour that gives so much of the ethereal quality to flowers. These qualities were to come later in the painting of the French school of the 19th century. However, in his time his pictures were unequalled for exquisiteness and grace of form, and were masterpieces of faultless finish. Rachel Ruysch (1664-1750) painted in a similar manner and is by some critics considered his equal. Van Huysum's influence was considerable; and flower pictures in his manner continued to be painted on into the 19th century. They are not as sumptuous, have not the same perfected finish and have not usually the same beauty of form. Often they have an increased harshness.

In France there is an evidence of greater concern for the living character of the flower, a sense of its lightness and delicacy, or, its heaviness, on its stem—a sense for the frailness of flowers that makes Huysum's seem almost moulded from thin metal. Such a painter as Laurent Melaine (1745-1809) gives evidence of this, as does Francois Pret, of whom there seems to be no existing biography or even dates, but, whose robust and richly painted flowerpiece in the Prado, places him as a master, and moves the art of flower painting a step forward. It is in France, in the second part of the 19th century that flower painting reveals a new and glowing character. The changes brought about in painting by the French painters of this time are well known. The naturalistic trend of Courbet; Manet's aesthetic interest in colour and his admiration of Japanese art, tending to rich vivid masses of pure colour; Monet's interest in light, and colour in light—all these had their influence on flower painting.

France produced, adding these new phases to those of the Dutch school, a group of flower painters that is unsurpassed. In the decade between 1830 and 1840 were born Edouard Manet (1832-83), Antoine Vollon (1833-1900), Fantin-Latour (1836-1904) and Claude Monet (1840-1926). Manet and Monet were the real influences for added characteristics of painting, but Fantin-Latour was the great painter of flowers. In Manet's flower painting rich arrangement of colour in a bright and surrounding light gives a sumptuous quality. His flowers are painted with great gusto, freshness and luminosity. His influence is perhaps stronger on the painters of flowers of to-day than that of any other painter; but Monet's influence has been of an unmeasurable quantity also. He made the world see colour in light, pure colour of a vibrating, iridescent quality. In his pictures he has perhaps painted flowers

rather more as a medium by which to express this feeling for pure colour in light and in space than because of the beauty of the flowers in themselves. Latour, on the other hand, understood flowers, their delicacy of form, growth and colour, and painted them for their own great beauty, but, in doing so, combined the qualities of his two great contemporaries. His pictures are beautiful arrangements of form and colour with all the living vibrating, if passing, qualities of the flower, placed in full light with atmosphere surrounding them, and they mark to the present time the high spot of Western flower painting.

Between the realistic Dutch period and the French impressionistic, William Henry Hunt (1790-1864) in England, painting in a method quite his own, produced flower pictures in water colour that, ungracious as they generally are, had much of the exactness of floral structure with a suggestion in colour, that was slightly related to what the French later developed to such a supreme degree. Later still, Francis E. James (1849-1920) developed in water-colour a crisp delightful phase of flower painting. Contemporary with the great French impressionists, John La Farge (1835-1910) in America was a true flower painter, and the forerunner of a number of flower painters in this country. Abbott Thayer, Wilton Lockwood, Maria Oakley Dewing, Charles Demuth and Laura Hills are artists who have found, in flowers, subjects for their paintings, and each has added something to the art. (See also PAINTING; WATER-COLOUR.)

(G. W. D.)

FLOWER-PECKER, the name given to the members of a family (*Dicaeidae*) of small Old World birds which usually build hanging nests. *Dicaeum erythrorhynchus*, the smallest bird in the Old World, weighing some 7 or 8 grams, is included in this family.

FLOWERS, ARTIFICIAL. Imitations of natural flowers are sometimes made for scientific purposes (as the collection of glass flowers at Harvard university, which illustrates the flora of the United States), but more often as articles of decoration. A large variety of materials have been used in their manufacture by different peoples at different times—painted linen and shavings of stained horn by the Egyptians, gold and silver by the Romans, rice-paper by the Chinese, silkworm cocoons in Italy, the plumage of highly coloured birds in South America, wax, small tinted shells, etc. At the beginning of the 18th century the French, who originally learnt the art from the Italians, made great advances in the accuracy of their reproductions, and towards the end of that century the Paris manufacturers enjoyed a world-wide reputation. About the same time the art was introduced into England by French refugees and soon afterwards it spread also to America.

The industry is now a highly specialized one and comprises a large number of operations performed by separate hands. Four main processes may be distinguished. The first consists of cutting up the various fabrics and materials into shapes suitable for forming the leaves, petals, etc. This may be done by scissors, but more often stamps are employed which will cut through a dozen or more thicknesses at one blow. The veins of the leaves are next impressed by means of a die, and the petals are given their natural rounded forms by goffering irons of various shapes. The next step is to assemble the petals and other parts of the flower, which is built up from the centre outwards; and the fourth is to mount the flower on a stalk formed of brass or iron wire wrapped round with suitably coloured material, and to fasten on the leaves required to complete the spray.

FLOYD, JOHN (1572-1649), English Jesuit, was born in Cambridgeshire. When at Rome in 1592 he joined the Jesuits, and by 1606 was a missionary priest in England. He had considerable fame as a preacher and teacher, and was frequently arrested. His last years were spent at St. Omer where he died on Sept. 15, 1649. His works are listed in Fellow's *Bibl. Dict. Eng. Caths.* (1885).

FLOYD, JOHN BUCHANAN (1807-1863), American politician, was born at Blacksburg, Va., on June 1, 1807. He was the son of John Floyd (1770-1837), governor of Virginia, 1830-34. In 1826 he graduated from South Carolina college, after which he practised law in Virginia and in Helena, Ark. He was a representative in the Virginia legislature, 1847-49, and governor of Virginia, 1849-52; afterwards he was again returned to the

FLOWER PAINTINGS OF THE FRENCH, DUTCH, AND SPANISH SCHOOLS; 17TH-18TH CENTURIES

1. Flowers by François Pret, French. In the Prado
2. Flowers by Daniel Seghers, Flemish (1590-1661). Like his teacher, Jan Breughel, Seghers frequently painted flowers in conjunction with religious subjects. In the Prado
3. Roses, tulips and other flowers in a wicker-basket, by Juan de Arellano, Spanish (1614-76). In the Prado
4. Flowers by Andrea Belvedere (1642-1732), Neapolitan school. In his paintings of flowers, fruits and birds the light is often reflected from mirrors or fountains. In the Prado
5. Vase of flowers (1716) by Margareta Haverman, Dutch (18th century), pupil of Jan van Huysum. In the Metropolitan Museum of Art
6. A garland of flowers by Jan Breughel, Flemish (1568-1625). He frequently painted garlands of flowers around portraits or pictures of the Madonna by Rubens and others. In the Prado
7. Another painting of flowers by Jan Breughel, often called *Breughel de velours*. In the Prado
8. Garland of flowers by Daniel Seghers (see also fig. 2), a pupil of Jan Breughel. In the Prado

MODERN AMERICAN FLOWER PAINTINGS

1. Larkspur, Canterbury bells and peonies, pastel by Laura Coombs Hills (1859—), painter of flowers in pastel and miniatures
2. Mountain rhododendrons, by George Walter Dawson (1870—), flower and landscape painter; owned by Harold Hill Blossom
3. Peonies, by Wilton Robert Lockwood (1861–1914), painter of flowers and portraits
4. Water-lily among reeds, by George Walter Dawson (1870—), flower and landscape painter; owned by George B. Garrett

State legislature. In 1857 President Buchanan appointed him secretary of war.

When Maj. Anderson on Dec. 26, 1860, transferred his forces in Charleston harbour from Ft. Moultrie to Ft. Sumter, the move that resulted in the outbreak of hostilities in the Civil War, Floyd claimed that the act was contrary to his orders. When the president and a majority of his cabinet upheld and defended Anderson's move Floyd resigned and returned to his Virginia home, becoming a secessionist in his sympathies. A few days previous to his resignation President Buchanan had requested a resignation because of certain financial irregularities in Floyd's department due to extremely careless administration. Whether the request had reached Floyd at the time he resigned and the Ft. Sumter incident merely furnished him with a pretext for a more honourable exit is not known. Charges made later that he had made use of his office to furnish arms to the South in anticipation of war were disproved by an investigating committee of the House of Representatives in Jan. 1861. Floyd was commissioned a brigadier-general in the Confederate service and employed first in operations in western Virginia. In Feb. 1862, he became commander of the Confederate forces at Ft. Donaldson. When resistance seemed useless he escaped with part of his forces, leaving Gen. S. B. Buckner to surrender to Grant. For this President Davis relieved him of his command. He died at Abingdon, Va., on Aug. 26, 1863.

See P. G. Auchampaugh, *James Buchanan and his Cabinet on the Eve of Secession* (1926); J. F. Rhodes, *History of the United States, 1850-77*, vol. iii.; R. M. Hughes, "Floyd's Resignation from Buchanan's Cabinet," *Tyler's Quarterly*, vol. v. (1923).

FLOYER, SIR JOHN (1649-1734), English physician and author, was born at Hinters in Staffordshire, and was educated at Oxford. He practised in Lichfield, and it was by his advice that Dr. Johnson, when a child, was taken by his mother to be touched by Queen Anne for the king's evil. He died on Feb. 1, 1734. Floyer was an advocate of cold bathing, introduced the practice of counting the rate of the pulse-beats, and gave an early account of the pathological changes in the lungs associated with emphysema.

His numerous writings include:—*Φαρμακο-Βάσανος: or the Touchstone of Medicines* . . . (1687); *A Treatise of the Asthma* (1st ed., 1698); *The ancient Ψυχρολουτρία revived, or an Essay to prove cold Bathing both safe and useful* (London, 1702; several editions; abridged, Manchester, 1844).

FLUDD or FLUD, ROBERT [ROBERTUS DE FLUCTIBUS] (1574-1637), English physician and mystical philosopher, son of Sir Thomas Fludd, treasurer of war to Queen Elizabeth in France and the Low Countries, was born at Milgate, Kent. After studying at St. John's College, Oxford, he travelled in Europe and read the works of Paracelsus. He subsequently returned to Oxford, and taking his medical degrees, practised in London. Following Paracelsus, he maintained that the universe proceeds from and will return to God. The act of creation is the separation of the active principle (light) from the passive (darkness) in the bosom of the divine unity (God). The universe consists of three worlds: the archetypal (God), the macrocosm (the world), the microcosm (man). Man is the world in miniature, all the parts of both sympathetically correspond and act upon each other. Fludd's pantheistic materialism was refuted by Kepler and Gassendi. Fludd was a man of varied attainments, interested in scientific experiments, and defending the Rosicrucians. De Quincey considers him to have been the immediate, as J. V. Andreä was the remote, father of freemasonry. Fludd died in London on Sept. 8, 1637.

See J. B. Craven, *Robert Fludd, the English Rosicrucian* (1902), where a list of his works is given; A. E. Waite, *History of the Rosicrucians* (1887); De Quincey, *The Rosicrucians and Freemasons*; J. Hunt, *Religious Thought in England* (1870). His works were published in 6 vols., Oppenheim and Gouda, 1638.

FLÜGEL, GUSTAV LEBERECHE (1802-1870), German orientalist, was born at Bautzen on Feb. 18, 1802, and died at Dresden on July 5, 1870. Flügel's chief work is an edition of the bibliographical and encyclopaedic lexicon of Haji Khalfa, with Latin translation (7 vols., London and Leipzig, 1835-58). His

works include also an edition of the Koran (Leipzig, 1834 and again 1893); *Concordantiae Corani arabicae* (Leipzig, 1842 and again 1898); *Mani, seine Lehren und seine Schriften* (Leipzig, 1862); *Die grammatischen Schulen der Araber* (Leipzig, 1862); and *Ibn Kullûbugas Krone der Lebensbeschreibungen* (1862).

FLÜGEL, OTTO (1842-1921), German philosopher, was born on June 16, 1842, at Lützen, and educated at Schulpforta and Halle. He became pastor at Wansleben, near Halle. While in his theological speculations Flügel finds a place for revelation, in his philosophy he is a strong Herbartian and opponent of monism. With Allihn, he edited for a time the *Zeitsch. für exacte Phil. im Sinne des neueren philosophischen Realismus*, and later edited Herbart's collected works. He died on July 9, 1921, at Dölau. His chief publications are: *Der Materialismus* (1865); *Das Wunder und die Erkennbarkeit Gottes* (1869); *Die Probleme der Philosophie und ihre Lösungen* (1876; 4th ed., 1906); *Die Seelenfrage* (1878; 3rd ed., 1902); *Die spekulative Theologie der Gegenwart* (1881; 2nd ed., 1888); *Das Ich und die sittliche Idee im Leben der Völker* (1885; 5th ed., 1912); *Das Seelenleben der Tiere* (3rd ed., 1897); *F. Herbart als Philosoph* (1905); *Monismus und Theologie* (1908).

FLUKE, a name given to several kinds of fish, flat in shape, especially to the common flounder; also to a trematode worm, resembling a flounder in shape, which, as a parasite, infects the liver and neighbouring organs of certain animals, especially sheep, and causes liver-rot. The most common is *Fasciola hepatica* (see TREMATODES). The name is given to a species of kidney potato; to the holding plates, triangular in shape, at the end of the arms of an anchor; and to the triangular extremities of the tail of a whale. The use of the word as a slang expression for a lucky accident appears to have been first applied in billiards to an unintentional scoring shot.

FLUME, a word formerly used for a stream, and particularly for the tail of a mill-race. It is used in America for a very narrow gorge between precipitous rocks, with a stream at the bottom, but more frequently is applied to an artificial channel of wood or other material for the diversion of a stream of water from a river for purposes of irrigation, for running a sawmill, or for various processes in the hydraulic method of gold mining (see AQUEDUCT).

FLUMINIMAGGIORE, a town of the province of Cagliari, Sardinia, 10 m. by road N. of Iglesias, and 5 m. from the W. coast. Pop. (1921) town 3,569; commune 5,918. It is the centre of a considerable lead and zinc mining district. Three miles to the south are the ruins of a temple erected probably in the time of Commodus. They seem to mark the site of Metalla (mines), a station on the coast road from Sulci to Tharros, and the centre of the mining district in Roman times.

FLUORANTHENE, known also as idryl, a solid hydrocarbon occurring with phenanthrene, pyrene, diphenyl, chrysene and other substances in "Stupp" fat (obtained in working up the mercury ores in Idria), and also in the higher boiling fractions of the coal tar distillate. Fluoranthene, $C_{15}H_{10}$, was discovered by R. Fittig in 1878, who, with F. Gebhardt and H. Liepmann, elucidated its constitution. From the tar distillate the chrysene can be fractionally precipitated, and the fluoranthene can be separated from most of the pyrene by fractional distillation in a partial vacuum. The two latter hydrocarbons are finally separated by fractional crystallization of their picrates. Fluoranthene crystallizes in large slender needles or monoclinic tables, melting at 109-110° C and boiling at 250-251° C (60mm.). On oxidation with chromic acid it forms a quinone, $C_{15}H_8O_2$, and an α -diphenyleneketo-carboxylic acid.

See A. E. Everest, *The Higher Coal Tar Hydrocarbons* (1927).

FLUORENE (ortho-diphenylene methane),

is a hydrocarbon, $C_{13}H_{10}$, obtained from coal tar, where it was first discovered by M. Berthelot in 1867. The "carbolic oil" fraction,

after removal of naphthalene and anthracene, is distilled, the greater portion of the fluorene coming over between 295° and 310° C. Separation from other constituents may be effected through its solid potassium compound by fusion with caustic potash at 280° C. Addition of water regenerates the fluorene, which is further purified through its picrate or by crystallization, when it forms white, lustrous laminae, melting point 115° C, boiling point 295° C.

Oxidation with chromic acid yields fluorenone (diphenylene ketone)

yellow prisms, melting at 84° C, but with potassium permanganate as oxidizing agent the molecule is broken down, giving phthalic acid (*q.v.*). The positions taken up in fluorene by entering substituents are controlled by the influence of the phenylene nuclei one upon the other, and not at all by the methylene group (contrast carbazole, *q.v.*). Thus on dinitration the nitro-groups replace the hydrogen atoms ortho and para to the single bond which directly unites the two nuclei, to give 2:5- and 2:7-dinitrofluorene. 2:7-Diaminofluorene has been used in the preparation of azo-dyes which, like those from benzidine, possess affinity for unmordanted cotton, but they have not yet found commercial application. When fluorene is reduced with hydriodic acid, decahydrofluorene, $C_{13}H_{20}$, is produced; other hydrogenated fluorenes are also known.

(H. A. HA.)

FLUORESC EIN, so called from the fact that its dark-red solutions in caustic alkalis, in which it dissolves readily, show a brilliant green fluorescence, especially when they are largely diluted with water. It is a yellow amorphous powder when precipitated from water, in which it is insoluble; from alcohol it crystallizes in small dark-red nodules. It was first made in 1876 by A. v. Baeyer by the condensation of phthalic anhydride with resorcinol at 195–200° C. The two reacting substances are either heated alone or with zinc chloride, and the melt obtained is boiled out with water, washed by dilute alcohol, extracted by means of sodium hydroxide, the solution acidified and the precipitate well washed with water. By repeating this process fluorescein may be obtained in a very pure condition. It is resorcin phthalein, $C_{20}H_{12}O_5$, with the structure shown below.

By brominating fluorescein in glacial acetic acid solution, *eosin* (tetrabromofluorescein) is obtained, which crystallizes from alcohol in yellowish red needles, and dyes silk, wool and mordanted cotton a fine pink colour. The corresponding iodo-compound is known as *erythrosin*. Other dyestuffs of this series are safrosine or eosin scarlet (dibromodinitrofluorescein) and rose Bengal (tetraiodotetrachlorofluorescein). With zinc dust and caustic soda, fluorescein is reduced to the leuco-compound fluorescein. For the coloured and colourless dimethyl ethers of fluorescein see O. Fischer and E. Hepp (1893–95). These ethers correspond with the quinonoid and benzenoid (non-quinonoid) modifications of fluorescein. (See DYES, SYNTHETIC.)

FLUORESCENCE AND PHOSPHORESCENCE, terms applied to the cases of emission of light, by illuminated substances, in which the emitted light is made up of colours not present in the illuminating radiation. The term phosphorescence is often used in general sense to denote the emission of light by living organisms, such as glow-worms, fire-flies, jelly fishes and deep sea fishes, and bacteria present in decaying matter. In these cases the phenomenon is the result of biochemical reactions, often, in the case of the higher organisms, under the control of the creature. We are not here concerned with phosphorescence in this

sense (*see* PHOSPHORESCENCE, ANIMAL), but solely with the emission of light by bodies in which no chemical changes take place, and where illumination is a necessary preliminary. Substances which do not exhibit fluorescence or phosphorescence merely reflect or diffuse the light which falls upon them, coloured substances extracting certain constituents of the light by absorption and reflecting the residue, the absorbed radiations being transformed into heat. We may regard white light as made up of a mixture of all possible colours, as this view, although perhaps not the most modern one, answers the purposes of the present case. A green pigment absorbs the red, orange, yellow, blue and violet constituents of the white light and diffuses the green rays. If illuminated by red or violet light, it appears black, as all of the light is absorbed. In the case of fluorescence and phosphorescence the absorbed rays, instead of being changed into heat, are transformed into light of a different colour, which is emitted by the substance in addition to rays reflected or diffused in the usual manner. The substance may be regarded as a light “transformer,” changing the wave-length of the rays, as the electrical transformer alters the voltage. Practically all substances exhibit the phenomenon to a greater or less degree, though it is usually masked by the faintness of the fluorescent or phosphorescent light in comparison with the light reflected or diffused. If only ultra-violet light, which the eye does not perceive directly, is used in a darkened room for the illumination, the phenomenon is at once apparent, practically everything in the room becoming immediately more or less luminous.

The term *fluorescence* has been applied to the cases in which the emission of the light created, so to speak, within the substance continues only as long as the exciting rays fall upon it, while the term *phosphorescence* is used for cases in which the luminosity persists for a longer or shorter time, after the light has been shut off. Modern researches have shown, however, that this classification is unfortunate, for we can cause a fluorescent substance to become phosphorescent by altering the medium in which it is dissolved, *e.g.*, by dissolving it in a gelatine solution and allowing the gelatine to dry. Moreover, many fluorescent substances, if examined by refined methods, are found to glow for a very brief interval of time, say $\frac{1}{10,000}$ sec. after the illuminating light has been cut off. This circumstance has resulted in a tendency on the part of some writers to regard the two phenomena as identical. This, however, is not the case, for it has been fairly well established that fluorescence is a phenomenon which occurs wholly within the molecule, the re-emission of the light sometimes being delayed for a very brief interval, while true phosphorescence, which is in general of much longer duration, results from the expulsion of an electron from the molecule, the phosphorescent light resulting from its return. These matters will be fully discussed later on.

History.—The phenomenon of phosphorescence was made the subject of scientific enquiry some 50 years before fluorescence was seriously investigated. The chapter opens with the discovery in 1602, by a cobbler of Bologna, Vincenzo Cascariolo, of a substance which shone brightly in the dark after exposure to a strong light. This shoemaker practised alchemy in his leisure moments, and having found on Mt. Pesara some fragments of a very heavy mineral which sparkled brilliantly in the sunlight, he took them home and heated them in his furnace in the hope of obtaining precious metals. The mineral was “heavy-spar,” a natural sulphide of barium, and the result of his experiment was the birth of the celebrated “Bologna stone,” the first of a series of so-called natural phosphors, the investigation of which at once became the fashion. These substances were usually porous in structure, and it was at first supposed that they soaked up light as a sponge soaks up water, but in 1652 Zecchi illuminated his phosphors with light of different colours and found that the colour of the phosphorescent light was the same in each case, thus proving that phosphorescence was not a re-emission of light stored up in the substance. This observation was confirmed and put on record by other observers, one of whom used coloured rays obtained from a prism for exciting the phosphorescence. This is of interest, as it was not until 200 years later that the discovery was made by Sir George Stokes that fluorescent bodies behaved in the same way.

The study of fluorescence commenced about half a century after the discovery of the Bologna stone, though allusions to the phenomenon can be found as far back as the year 1570, when a Spanish physician, Niccolo Monardes, mentioned the blue-colour exhibited by a tincture of a certain wood (*lignum nephriticum*). Grimaldi in 1665 investigated the optical properties of this tincture, illuminating it in a darkened room with a beam of light concentrated by a lens, and described the blue luminosity of the cone of rays within the liquid. In 1704 Newton investigated the phenomenon, illuminating the solution with light of various colours, and attributing the effects observed to an internal reflection of the light. Nose in 1780 discovered the fluorescence of tincture of sandal wood and quassia. In 1792 an advance was made by Wünsch, who employed more or less homogeneous light obtained by a prism for the illumination. He described the effects observed, but was unable to explain them.

In a paper communicated to the Royal Society of Edinburgh in 1833, Sir David Brewster described what he believed to be a new phenomenon to which he gave the name of "internal dispersion." By condensing sunlight with a lens on a bottle filled with a solution of chlorophyll, the green colouring matter of leaves, he observed that the path of the rays through the green liquid was marked by a cone of a blood red colour. He subsequently observed the same phenomenon in other liquids, and in some solids, notably fluor-spar, and named it "internal dispersion," being of the opinion that it was due to coloured particles held in suspension. Several years after Brewster's observations, Sir John Herschel discovered independently that a colourless solution of sulphate of quinine, when held in a strong light, showed a shimmer of blue at the surface at which the light entered. The illuminating beam, after its passage through the solution, was unable to provoke the blue colour in a second bottle of the liquid, though it was apparently unchanged either in colour or intensity. Herschel considered that the light had been modified in some new and mysterious manner at the surface of the liquid, and introduced the term "epipolized" (*ἐπιπολή*, surface) to designate it. He concluded that light which had once been epipolized, could not be epipolized a second time.

None of these early investigators had a glimmering of an idea that the phenomenon was an emission of a new set of radiations excited by the absorption of violet and ultra-violet rays. Newton and Wünsch were on the right track in their investigations with coloured light, and it is hard to see how they failed to find the key to the mystery. The latter investigator must have missed it by a very narrow margin, for the same method, in the hands of Sir G. G. Stokes, established the true nature of the phenomenon. His first paper "On the Change of Refrangibility of Light" was published in 1852. This brief title is a complete statement of the true nature of fluorescence. Extending the experiments of his predecessors he soon came to the conclusion that he was dealing with a wholly new phenomenon, the scattered beam of light differing in refrangibility (colour) from the rays which excited it. He at first spoke of it as "true internal dispersion" to distinguish it from the scattering of light by cloudy solutions which he called "false internal dispersion." He afterwards abandoned this term as misleading, substituting for it the term *fluorescence* (derived from fluor-spar, a mineral which exhibits the phenomenon), a term which does not presuppose any theory.

In one of Stokes's experiments a vertical spectrum was projected on the flat side of a glass tank filled with the solution, the fluorescence being observed through the side. Rays for which the absorption was slight penetrated the liquid to the opposite wall, and excited feeble fluorescence along their entire path. More powerfully absorbed rays penetrated to lesser and lesser distances, and excited fluorescence of increasing intensity, the gradual retreat of the fluorescence to the front wall being marked by a curved line. This line shows objectively the actual form of the absorption curve. The photograph (Plate I., fig. 1) was made with a solution of rhodamine, the absorption band of which has two maxima as is clearly indicated. The position and colour of the exciting rays are indicated by arrows, and the absorption curve by dots.

Stokes's Law.—On exciting the fluorescence with monochromatic light, by restricting the excitation to a very narrow region of the spectrum passed through a fine slit, Stokes observed that the spectrum of the fluorescent light covered a fairly wide range in the blue region, which showed that light of many different shades of colour was produced by illumination with a single pure colour. Stokes was of the opinion that the fluorescent radiations were always of less refrangibility (longer wave-length) than the exciting rays, a condition governed by what has been known as Stokes's law, the validity of which was first called into question by Lommel.

Many experimenters busied themselves with this question, and a controversy commenced which lasted for 20 years, Hagenbach and Lommel being the principal disputants, the former claiming that the law of Stokes was never violated, and that all of Lommel's results were due to the impurity of the light used for exciting the fluorescence. Lommel, however, excited the fluorescence of a solution of naphthalene red with the light of a sodium flame (which emits a nearly monochromatic yellow radiation) and observed that the fluorescence spectrum extended from the red to the yellow-green region. In answer to objections by Hagenbach, he further showed that it was the yellow sodium light that was responsible for the green rays in the fluorescence, as the bunsen flame without the sodium caused no fluorescence at all. The more recent experiments of Nichols and Merritt, who measured with a photometer the intensity of the light at different points of the fluorescence spectrum, when excited by light of different colours, showed that Lommel was right and that Stokes's law did not hold in a number of cases. They found that the intensity curve of the fluorescent spectrum, by which we indicate the relative intensities of the different colours, was independent of the colour of the exciting light, though the total intensity varied over a wide range as the exciting wave-length was altered. They found, moreover, that the absorption band overlapped the fluorescent band in the case of all substances which showed violation of Stokes's law.

To show the failure of the law it is not necessary to resort to laborious measurements with the photometer. The spectrum photographs (Plate I., fig. 2) bring out the effect most conspicuously. They were made by directing the spectroscope at a small bottle filled with a dilute solution of fluorescein, which was illuminated with an intense beam of monochromatic light emerging from a second spectroscope, the eye piece of which had been replaced by a narrow slit. By turning the prism of this instrument, the colour of the exciting beam could be changed gradually from blue to green, and finally yellow. A suspension of fine particles in the fluorescein solution scattered a small amount of the exciting light, causing it to register its position in the spectrum with respect to the fluorescent spectrum. It appears in the photographs as a rather broad, hazy line, either immersed in the fluorescent band, or well outside of it, according to its colour. In the upper picture, the exciting light is entirely outside of the fluorescent range in the blue region; in the next two it has entered it, and in the fourth it has advanced so far towards the yellow that fluorescence is no longer produced. It is apparent from the two middle pictures that the broad fluorescence band is fully developed on both sides of the exciting line. The colour of the fluorescence is yellow-green. The faint line to the right of the fluorescence band is the D line of sodium, which was impressed on each plate to facilitate bringing them into coincidence.

Fluorescence of Gases and Vapours.—In spite of the very large amount of experimental work which had been done on fluorescence up to 1928, there was at that time no very satisfactory theory of the phenomenon in the case of liquids and solids. In the case of gases and vapours, however, where the molecules are not under the influence of their neighbours, the mechanism of the transformation of the radiations was beginning to be elucidated. The simplest case of all, involving no change of wave-length or colour, is that in which the vapour absorbs one or more definite radiations and re-emits them without altering their frequency. This is the phenomenon of *resonance radiation*, observed for the first time in the case of sodium vapour by R. W. Wood in

1905 (*Phil. Mag.*, vol. xx.), and several years later in the case of mercury vapour. Though it is not strictly fluorescence, a brief consideration of the process involved will serve as a useful foundation upon which to build a discussion of the more complicated types. If a little metallic sodium is heated in a highly exhausted glass bulb to a temperature of 140°C , and the yellow light from a small sodium flame is focussed at the centre of the bulb with a large condensing lens, the path of the rays through the vapour is marked by a cone of yellow light, the appearance being as if the bulb were filled with a light smoke or fog. (Plate I, fig. 3 gives a good idea of the phenomenon, though it shows the fluorescence of iodine instead of sodium vapour.) If, however, we substitute a source of light of any other colour for the sodium flame, we see nothing at all. The vapour is totally unable to scatter light unless its wave-length is precisely the wave-length of the so-called D lines of the solar spectrum, or the yellow light of the sodium flame.

The process involved was formerly supposed to be analogous to what takes place when sound-waves from one tuning fork impinge on a second fork of the same pitch, the latter absorbing some of the sound from the air, and being thrown into vibration itself in the process, so that if we quench the first fork with the fingers we hear the singing of the second. The modern theory, which we owe to Niels Bohr, is not quite so simple. By the absorption of the radiation the sodium atom is brought from its normal state, in which the electron revolves about the nucleus in an inner orbit, to an excited state in which the electron moves in an orbit more remote from the nucleus, the resonance radiation being emitted when the electron returns to its original orbit. (*See ATOM.*) This makes the processes of absorption and re-emission successive instead of simultaneous as on the older theory. In the case of mercury vapour the same thing happens, except that it is an invisible radiation in the ultra-violet which is absorbed, and the mercury vapour is contained in an exhausted bulb of fused quartz, which requires no heating as the density of the vapour is great enough at room temperature to show the phenomenon at its best. The bulb is illuminated by the ultra-violet ray of wave-length 2536 \AA.U. from a quartz mercury arc. This ray is separated from the others by a prism and focussed at the centre of the bulb by a quartz lens. A photograph made with a camera provided with a quartz lens shows the cone of resonance radiation stretching right across the bulb. If the bulb is heated slightly, the resonance radiation retreats to the wall at the point where the radiation enters it, as the rays are no longer able to penetrate more than a very minute depth of the vapour. If the bulb is cooled it is found that the resonance radiation of the vapour can be detected at a temperature of -50°C , that is, 10° below the freezing point of mercury. This showed that even the solid metal gave off sufficient vapour to absorb and re-emit the light. Bulbs rendered luminous in this way have been named "resonance lamps," and have proved of use in various investigations as they give off radiations even more homogeneous, or monochromatic, than the lamps which excite them.

The next step in the development which we must consider is the observation made in 1915 by R. J. Strutt (now Lord Rayleigh) that sodium vapour, illuminated by the ultra-violet light of a zinc spark (which emits a radiation of the same wave-length as one of the sodium ultra-violet lines), emits a yellow light of the same wave-length as when excited to resonance radiation by the yellow light of a sodium flame. This is the simplest and most elementary case of fluorescence which we have, and its explanation is clear from the viewpoint of Bohr's theory. By the absorption of the ultra-violet light the electron is raised to a higher orbit than that in which it originally revolved. The return to the normal state may now take place in either of two ways. It may return directly, in which case ultra-violet resonance radiation occurs, or it may be shaken out of this orbit into a lower one by collisions with other atoms, and from here return to the inner orbit with the emission of the yellow light. In this case Stokes's law is obeyed, for it has not yet been found possible to get the ultra-violet line by excitation with yellow light.

Slightly more complicated is the case observed by Fuchtbauer,

who found that mercury vapour *in vacuo* in a tube of fused quartz glowed with a green light when illuminated by the total radiation of a quartz mercury arc, and the spectroscope showed that practically all of the spectrum lines of the mercury arc were being emitted by the vapour. These other rays are not emitted as resonance radiation, however, for if a glass plate, which cuts off the ultra-violet but not the visible rays, is interposed between the arc and the tube containing the vapour, the luminosity vanishes, although the vapour is still powerfully illuminated. For these other rays to be produced it is necessary that the vapour be illuminated by the ultra-violet ray λ_{2536} , and the glass plate absorbs this. The processes involved in this case are completely in accord with Bohr's theory of absorption and re-emission. Mercury vapour in the normal state absorbs only ultra-violet light, by which it is brought into the excited condition (electrons in higher orbits), and while in this condition it can absorb some, but not all, of the visible radiations. By the absorption of the violet ray λ_{4046} , the electron is carried to an orbit still further removed, and it may return to any one of three inner orbits, the green line being emitted in one case. We are here dealing also with a very simple case of fluorescence, namely the emission of green light resulting from the absorption of blue. Fuchtbauer's observations have been extended by R. W. Wood, who illuminated the vapour by various combinations of rays from the lamp and studied the orbital transitions of the electrons which resulted. One of the most striking and interesting results of the study was the discovery that emitted light, which resulted from two successive absorption processes, increased as the square of the intensity of the exciting light, while certain other spectrum lines, the emission of which required three successive absorptions, increased as the cube, a circumstance perfectly in accord with theory.

Resonance radiation and the simple types of fluorescence exhibited by sodium and mercury vapour, which have just been described, are phenomena of the atom, the vapours of sodium and mercury at low pressure being monatomic. When these vapours are formed at higher pressure by raising the temperature of the bulbs, some of the atoms combine to form diatomic molecules, and a new type of absorption and fluorescence manifests itself. If white light is passed through the dense sodium vapour and examined with a spectroscope, a very complicated absorption spectrum consisting of fluted bands is seen, and a similar spectrum can be seen with the vapour of iodine at room temperature. These bands we now believe to be the result of three different disturbances produced in the molecule, an orbital displacement of the electrons in the atoms, a vibration of the two atoms along the line joining them, and a rotation of the molecule as a whole. (*See BAND SPECTRUM.*) If sun or arc light is concentrated upon the vapour, it glows with a greenish light, the spectrum of which consists of bands similar in their general appearance to the absorption bands. A photograph of the fluorescence of iodine vapour at room temperature in a large glass bulb is shown (Plate I, fig. 3). The path of the illuminating beam from the arc to the bulb was made visible by blowing a little smoke into the region between them. The bulb is highly exhausted, and contains a small crystal of iodine. If air is admitted to the bulb, even in a minute quantity, the fluorescence disappears. This is true fluorescence, for if we illuminate with monochromatic light, we find many other wave-lengths or colours in the emitted light, the vapours giving out light which the spectroscope shows as double lines spaced at sensibly equal intervals along the spectrum (R. W. Wood, *Phil. Mag.*, 1912). These spectra have been fully accounted for theoretically by Lenz, and have proved useful in the analysis of the very complicated band spectra, which are made up of fine lines to the number of some 50,000 or 60,000 in the case of iodine. Stokes's law is violated conspicuously in the case of these resonance spectra, for lines frequently appear on the short wave-length side of the line which excites the vapour. If helium or some other chemically inert gas is mixed with the iodine vapour, and illuminated say with the green line of the mercury arc, the widely spaced double lines fade away and the band spectrum appears in its place. This forms the stepping-stone between the vapour fluorescence, and the fluorescence of a liquid or solution,

for by the introduction of the helium we note the effects of the collisions of the molecules on the emission spectrum, and in a solution we have this same effect to an enhanced degree. It appears that the effect of the collisions, in the case of iodine, is to change the rotational energy of the molecules by different amounts, with the result that, during their return to the normal state, each one emits a radiation of a definite frequency depending upon the change in its rotational energy produced by the collision. In general, the effect of an impact with another molecule is to decrease the internal energy of an excited molecule, which will result in the emission of a radiation of lower frequency than that of the exciting light, the excess energy being spent in increasing the velocity of the rebounding molecules, *i.e.*, in raising the temperature of the vapour. It may happen in some cases that some of the kinetic energy of the colliding molecules is spent in raising the energy of vibration or rotation, and this gained energy is given off again when the molecule returns to its normal state. It is in this way that we may have the higher frequencies radiated contrary to Stokes's law, without violating the energy relations of the quantum theory.

The case of benzene is of especial interest as it exhibits fluorescence in the vapour, fluid and solid state, and also when in solution in another liquid. The behaviour of the vapour under optical excitation resembles that of iodine in some respects, and a study of the substance in its several states has shown that it may possibly be regarded as a connecting link between the phenomena exhibited by sodium and iodine vapours, which are comparatively well understood, and those presented by aniline dyes and other complicated organic compounds, in regard to which we have no very complete or satisfactory theory.

Efficiency Factor.—By this we mean the ratio of the absorbed energy to that which is re-emitted as fluorescence. If we illuminate a solution of fluorescein with monochromatic light obtained from a spectroscope, we find that the intensity of the fluorescence varies greatly as we alter the colour of the exciting light. As we have seen, the complete fluorescence spectrum is radiated regardless of the wave-length of the exciting light, if it is capable of exciting any fluorescence at all, and it is this circumstance that causes Stokes's law to break down in cases when the absorption band and fluorescence band overlap. It was shown by Nichols and Merritt that all wave-lengths are equally efficient in exciting fluorescence if we compare the fluorescence with the amount of light actually absorbed. Now in the case of resonance radiation of a metal vapour in a high vacuum it has been found that all of the energy extracted from the exciting beam of light is re-emitted, there being no true absorption, but if some other gas is present, true absorption at once appears and the intensity of the resonance radiation is diminished. In the case of fluorescence the efficiency was determined for a number of substances by Wawilow (*Zeit. für Physik*, 1924), who measured the amount of the absorbed light with a photometer and compared it with the fluorescent light scattered by the solution, and by a diffusing screen of magnesium oxide. The highest efficiency was found for fluorescein which showed an efficiency of 75%, while some dyes showed values as low as 2% or less. An efficiency of 75% means that three-quarters of the energy of the absorbed light is re-emitted as fluorescent light. It is this high efficiency which makes possible the Cooper-Hewitt "light transformer" which is described under *Applications of Fluorescence*.

The intensity of the fluorescent light in the case of most solutions varies enormously with the concentration, and falls to zero if the concentration becomes too great. This can be well shown with fluorescein, which exhibits its most brilliant effect only in extremely dilute solutions, and becomes non-luminous if the concentration is increased beyond a certain point. We are quite in the dark in regard to the cause of this effect. All that can be said is that the close proximity of the fluorescent molecules prevents the re-emission of radiation, the mystery being why a fluorescein molecule interferes with the functioning of its neighbours any more than the water molecules. A similar behaviour in the case of benzene has already been mentioned.

Fluorescence of Uranium Compounds.—Though there are

countless organic compounds which show fluorescence, very few inorganic substances exhibit the phenomenon, though many of them have absorption bands of the same general character as those of the fluorescent organic compounds. Until we can explain why a solution of potassium permanganate, with its beautiful absorption bands in the green region of the spectrum, shows no trace of fluorescence, while a solution of rhodamin which has similar absorption bands and colour, glows vividly under illumination, we cannot claim to have a very definite view of the underlying causes. It seems probable that in fluorescent bodies, such as benzene and other aromatic compounds, and certain salts of uranium, the electron system of the atom which causes absorption and fluorescence is shielded in some way from the disturbing influence of neighbouring atoms. The salts of uranium and the platino-cyanides are among the few inorganic compounds which show conspicuous fluorescence, and it is only the uranyl salts that show the phenomenon, the uranous compounds exhibiting no trace of luminosity.

Various compounds of uranium were studied by Stokes, who found that some of them exhibited fluorescence in solution as well as in the crystalline state. He found that the spectrum consisted of well-defined bands arranged at regular intervals, and that the absorption spectrum in the blue and violet region exhibited a series of bands of similar appearance. An exhaustive study of the subject was undertaken in 1872 by E. Becquerel, who discovered that the fluorescent crystals of the uranyl salts were also phosphorescent, that is they continued to glow for several thousandths of a second after the illuminating rays had been cut off. He found also that the fluorescent and phosphorescent spectra were identical in structure, from which he concluded that the two phenomena were not really distinct. According to our present views, however, we should not call this phosphorescence, but fluorescence of long duration. In more recent times a very comprehensive study of these salts has been made by Nichols and Merritt. In 1903 the very important observation was made by J. Becquerel and Kammerlingh Onnes, working with uranyl salts in the cryogenic laboratory of the latter at Leyden, that at the temperature of liquid air (-185°C) each band of the fluorescent spectrum broke up into a number of narrower bands. At the temperature of liquid hydrogen the components of the band became almost as narrow as the lines of a spark spectrum.

The chief point of interest in connection with the fluorescence of the uranyl salts is the similarity of their behaviour to that of benzene. The broad bands at room temperature, the breaking up of these bands into narrower bands at low temperature, the overlapping of the region of absorption and fluorescence are common to both substances. While the fluorescence of the crystals of the uranium salts is very bright, that of their solutions in water is in general very feeble. Francis Perrin has found that solutions in sulphuric acid fluoresce much more powerfully, and that the fluorescence is of long enough duration to be seen with the phosphoscope, an instrument which will be described presently. This is the first case recorded of a "phosphorescent" liquid. It is probable that the UO_2 molecules in this case are in an environment similar to that obtaining in the case of uranium (or "canary") glass, which also exhibits a fluorescence of long duration in the phosphoscope.

The platino-cyanides of barium, magnesium, potassium and other metals form another group of fluorescent crystals. These compounds differ from the uranium salts in that they show no trace of luminosity in solution, and their solutions are as clear and free from colour as pure water, though the salts are highly coloured. In some respects they resemble the true phosphorescent compounds, which we shall now consider.

Phosphorescence.—This term, as formerly applied, would cover all cases in which the emission of light persisted, even if only for a minute fraction of a second, after the exciting light had been cut off. As has been said, if we adopt this definition, no sharp line can be drawn between fluorescence and phosphorescence. The term, as now used, applies to a class of bodies in which very minute traces of metallic impurities in crystalline substances give them the power of emitting light for a longer or shorter time after

exposure to a strong illumination. Such substances are termed "phosphors."

Many of the substances studied by A. C. Becquerel, in his pioneer investigations, we should now class as fluorescent. He devised an instrument which he named the phosphoscope, in which the substance was contained in a dark box between two wheels perforated by slots which were arranged out-of-step; these wheels were mounted on a common axle, and could be rotated at high speed by a system of gears. The illuminating beam reached the substance through the slots of one of the wheels, while the observations were made through the perforations of the other. This enabled the viewing of the substance in the dark in the very brief intervals between the flashes of light which illuminated it. With this instrument Becquerel discovered the phosphorescence of an enormous number of substances, and measured the duration of the phenomenon, as affected by the temperature, colour of the exciting light and other factors.

Crystals of uranium nitrate, fluor spar, gems and many other minerals glow with brilliant colours in this instrument. The foundations of our knowledge regarding the nature of the true phosphorescent bodies, as distinguished from fluorescent bodies showing a slight persistence of luminosity, was laid by the researches of P. Lenard and his collaborators. They found that the phosphorescent properties of the metallic sulphides were due to very minute traces of other metals by which they were rendered active. The maximum intensity of the phosphorescence is obtained with a certain definite proportion of the impurity, an excess decreasing it. In some cases phosphorescence is produced by as little as $\frac{1}{10,000}$ % of the impurity.

The earlier work on phosphorescence was hampered by the imperfect methods of purification of the chemicals employed in the preparation of "phosphors." It was found difficult to duplicate results, and the production of a satisfactory phosphor by following a recommended specification was often a matter of luck. The researches of Becquerel, Verneuil, Boisbaudrans and Wiedemann gave evidence of the part played by impurities, but Lenard was the first to examine the conditions systematically, preparing his phosphors from carefully weighed amounts of the purest materials obtainable. He employed metallic sulphides, oxides and selenides as the foundation material, adding minute traces of other metals as the activating substance, the mixture being heated, usually with a flux of sodium chloride or sulphate, to a high temperature in a furnace. Phosphors can also be prepared by crystallization from solutions, and this method was the one usually employed by Wiedemann. These, however, do not exhibit as brilliant a phosphorescence as those obtained by the furnace method. Cadmium sulphate, recently studied by Waggoner, is a good example of phosphors of this class. The purest salt obtainable commercially, phosphoresces when illuminated by ultra-violet light, but if further purified by repeated fractional crystallization, shows no trace of luminosity. The addition of 0.1% of zinc sulphate causes the appearance of an intense blue phosphorescence; magnesium or sodium salts added as impurities cause yellow or green phosphorescence.

The present view is that all of these phosphorescent bodies are crystalline, the molecules of the impurity deforming the crystal lattice. This, while contrary to the former views of Lenard, who considered his phosphors amorphous, has been confirmed by X-ray photographs made by the method of Debye and Scherrer. An interesting case is that of calcium tungstate, the material used in the preparation of X-ray fluorescent screens. Obtained as an amorphous or non-crystalline precipitate from solution, and even if activated by impurities, it shows no trace of phosphorescence. On allowing it to stand for some time it changes gradually into the crystalline modification, as shown by X-ray photographs, in which state it exhibits phosphorescence. The change can be accomplished more rapidly by heating the amorphous powder, but the temperature must not exceed 1,000° C.

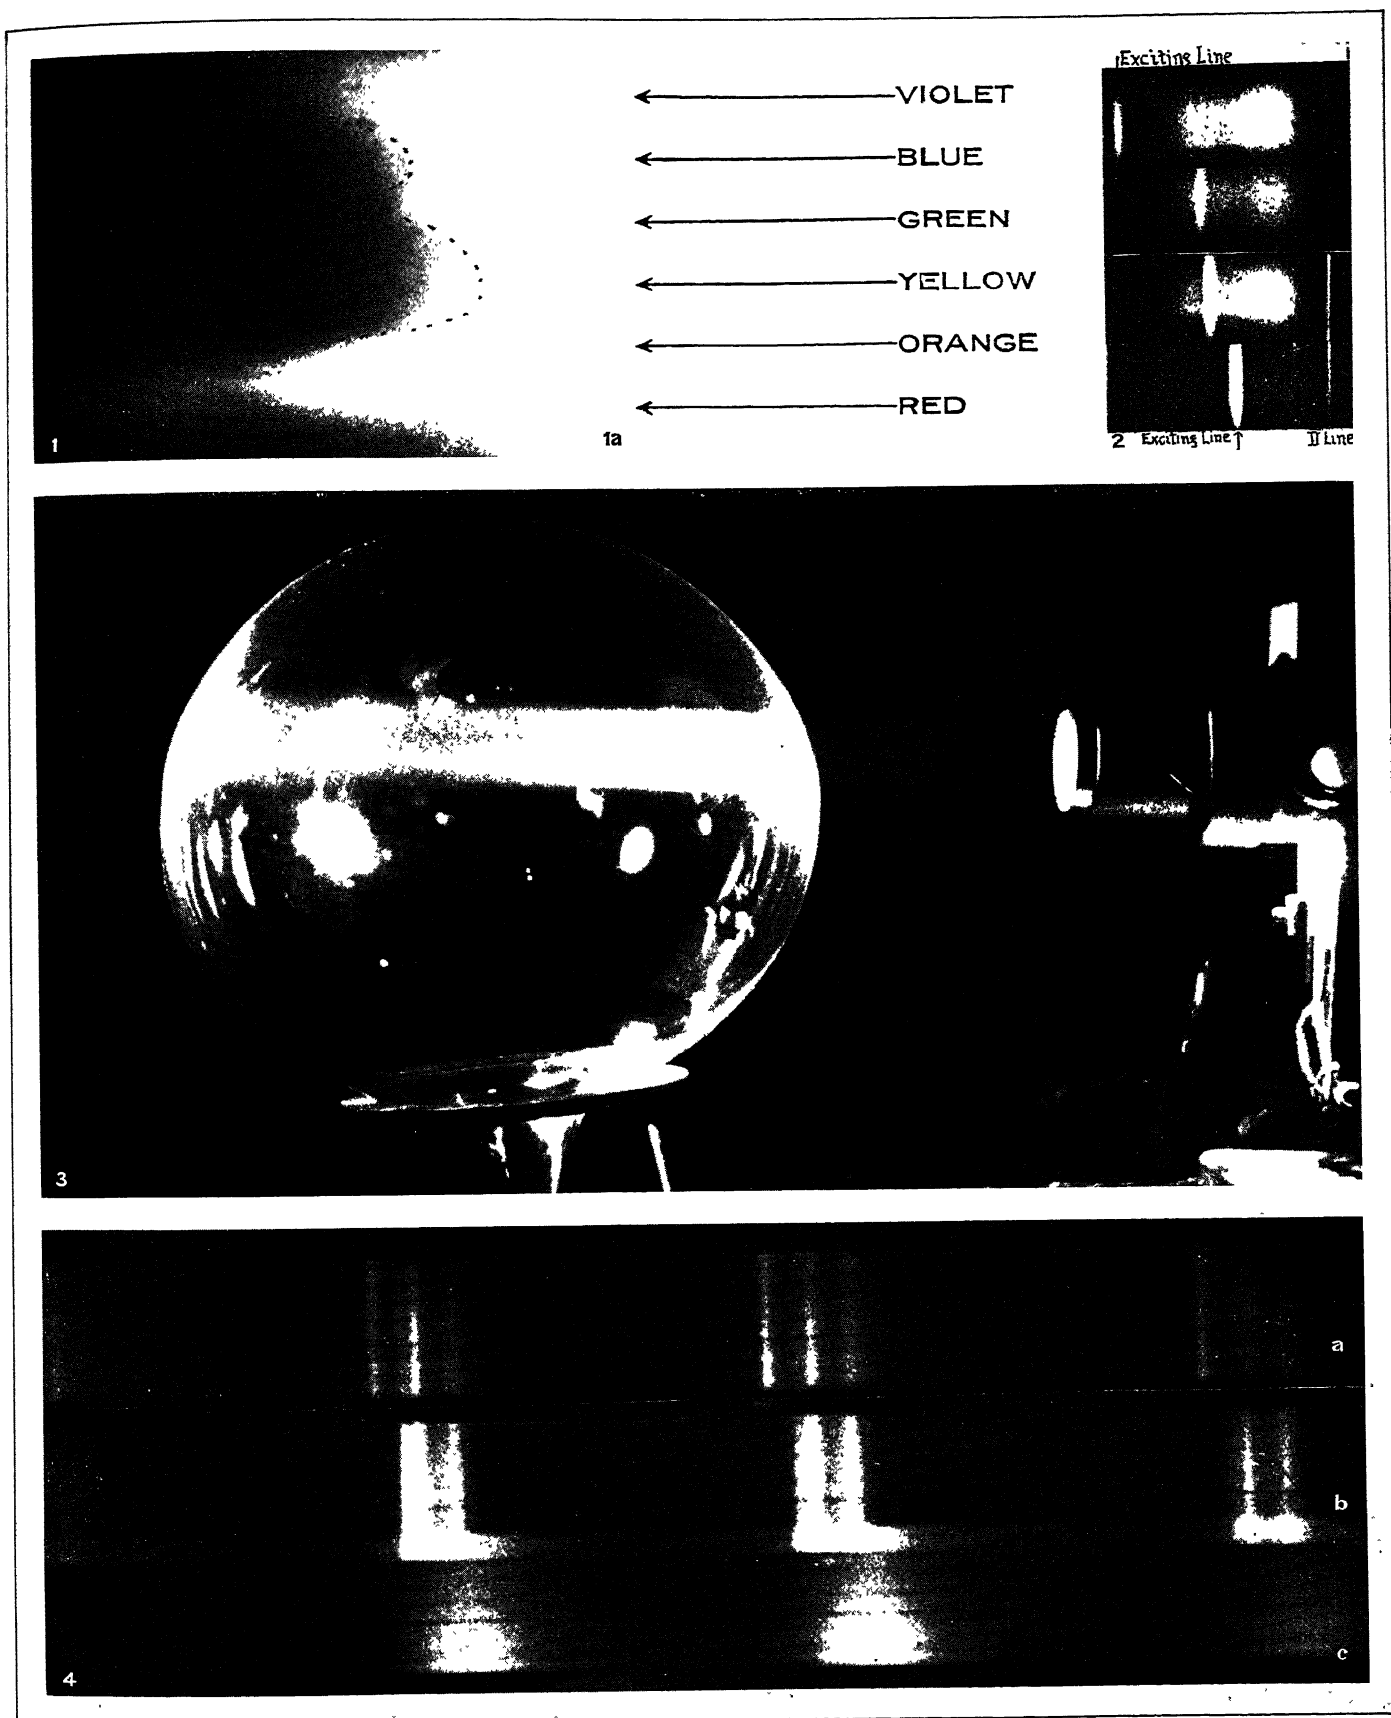

Quenching of Phosphorescence by Red and Infra-red Rays.—Seebeck discovered that orange or red light falling upon a phosphorescent substance, excited to luminosity by violet or blue light, destroyed the phosphorescence completely. This dis-

covery, though recorded in Goethe's *Farbenlehre*, remained comparatively unknown, and the phenomenon was rediscovered many years later by E. Becquerel, who investigated it more fully and found that the quenching of the phosphorescence by orange or red light was preceded by a momentary increase in the intensity of the luminosity followed by complete darkness. It appeared as if the red rays squeezed out all of the stored light in a few moments, and he attributed the effect to the heating action of the rays, for he had found that the same thing could be accomplished by warming the substance. He found further that the infra-red rays acted in the same manner and his son, H. Becquerel, continued the investigation, and in 1883 studied the invisible region of the solar spectrum, beyond the red as far as 1.5μ (wave-length double that of the extreme visible red), by projecting the spectrum on a luminous screen excited to phosphorescence, and observing the darkening produced by the invisible rays. J. W. Draper improved the process by laying the partially darkened phosphorescent screen upon a photographic plate thus obtaining a permanent record. This method of phosphoro-photography of the infra-red was subsequently employed by Lommel, Dahms and others, but nothing of much importance has been accomplished by it.

Dahms in 1904 made the interesting observation that the luminosity of the zinc sulphide phosphors is quenched by red and infra-red radiations without any momentary increase, which shows that there are two distinct types of quenching. Balmain's luminous paint is an example of the first type. Under infra-red illumination, the phosphorescing material suddenly gives out a greenish light, quite different in colour from the violet glow which it emitted before the infra-red rays played upon it. If warmed slightly with a heated glass rod there is also an increase in luminosity, but in this case the colour is unaltered. This proves that the action of the infra-red rays is not merely a heating effect. The zinc-sulphide phosphors, which are now extensively used for stage effects, are examples of the second type of quenching. They rapidly darken under the action of infra-red rays without any preliminary increase of luminosity.

Lenard discovered that the absorption spectrum of an excited (*i.e.*, luminous) phosphor was different from that of the unexcited. The absorption bands in the ultra-violet disappeared under powerful illumination, and were replaced by new bands in the longer wave-length region. It is from absorption by these new bands that the quenching results. This change in the molecular state also manifests itself in other ways. The magnetic and dielectric properties of the phosphors are found to be different before and after illumination. Elster and Geitel found that both natural and artificial phosphors exhibited the photo-electric effect, *i.e.*, they gave off electrons when illuminated, and Lenard, following the matter up, found that the photo-electric emission and the phosphorescence were caused by absorption of radiation of the same wave-lengths. His theory of phosphorescence supposed that the absorption of light resulted in the ejection of an electron from an atom, and its capture by a neighbouring atom, the phosphorescence resulting from the gradual return of the captured electrons to their former places, the energy set free in this process being communicated to another electron and eventually radiated as light of longer wave-length.

The modern theory of the phenomenon rests chiefly on the recent work of Gudden and Pohl, who found that many non-phosphorescent (*i.e.*, "pure") crystals conducted electricity when illuminated by light. This may be called an "internal photo-electric effect," the electrons set free by the light, travelling through the crystal lattice to the anode, under the influence of the applied electro-motive force. It is only in a crystal, the space lattice of which is distorted by foreign atoms (impurities), that the return of the electrons ejected by the light causes an emission of radiation. Experiments on the electrical conductivity of these crystals have shown that the electrons do not traverse the distorted lattice freely, as in "pure" crystals, but that many are captured on their way to the anode by atoms. It has recently been found by Rupp that the electric current, which flows in a phosphorescent crystal (under an applied electric force) during its illumination, and ceases as soon as the illuminating rays are cut off, starts up

SPECTROSCOPIC COLOURS REFRACTED FROM FLUORESCENT ELEMENTS

1. Stokes' experiment. A vertical spectrum projected on solution of rhodamine producing band of colours (1a) having two maxima.
2. Four photographs of fluorescein solution illuminated by intense beam of monochromatic light emerging from a second spectroscop.
3. Resonance radiation, showing fluorescence of iodine vapour in a bulb illuminated by sodium flame, producing cone of yellow light.
4. Fluorescence of uranium, showing bands at regular intervals. The absorption spectrum, also phosphorescent, has a similar appearance.

FLUORESCENCE AND PHOSPHORESCENCE

SPECTRUM AND OBJECT PHOTOGRAPHS MADE THROUGH MERCURY VAPOUR
AND ULTRA VIOLET RAYS

1, 2, 3, 4, 5. Spectrum photographs made through mercury vapour, showing colour lines produced by fluorescence. Width of bands is determined by opening or slit in the aperture of the photographic spectroscope. 6, 7, 8. Photographs made under mercury arc lamp giving intense ultra violet radiations. Lamp is contained in a quartz tube and light is filtered through glass coloured black with oxide of nickel. 6. China plate photographed in

white light using scientific journal for background. 7. The same objects photographed under ultra violet light. Writing on paper attached to plate is made with solution of anthracene. 8. Photograph showing fluorescence of lens of the human eye. The skin appears quite dark while teeth are brightly reflected

again if the crystal is warmed or illuminated by infra-red rays, and that the amount of electricity transported is proportional to the amount of light emitted.

If a "pure" crystal is illuminated in the absence of an electric field the electrons ejected from atoms by the light move about freely in the lattice, and the local fields, which result from the ejections, recapture them as soon as the illumination ceases, and no current will flow under an applied electric force when the crystal is warmed. In the distorted lattice of a phosphorescent crystal, on the contrary, the ejected electrons are captured by other atoms, and if such a crystal is illuminated for a definite time, and the photo-electric current, which flows during the illumination is measured, an equal amount of electricity will flow, on cutting off the illumination and warming the crystal.

Applications of Fluorescence and Phosphorescence.—

Fluorescence can be utilized for illustrating or studying the passage of rays of light through liquids. The curved rays of light forming focal points in a non-homogeneous medium (*see* R. W. Wood, *Physical Optics*) were made in this way, a small amount of sulphate of quinine having been added to the solution. The ultra-violet portion of the spectrum can be rendered visible, and a small pocket spectroscope has recently appeared provided with a fluorescent screen for examining the spectra of sources of light rich in ultra-violet rays. The fluorescence of mineral oils is made use of in a process for the photography of the extreme ultra-violet in investigations with the vacuum spectrograph. Ordinary plates are insensitive to these rays as the gelatine film, in which the sensitive silver salts are embedded, is opaque to the light, but if a thin film of oil is smeared over the film, it becomes fluorescent when the spectrum lines are focussed on it, and this fluorescent light records itself on the plate.

Fluorescence has even been utilized for purposes of general illumination. The mercury arc, one of the cheapest artificial sources of light, suffers from the disadvantage that it gives out little or no red light, with the result that under its illumination, few objects appear in their proper colours, and the human face takes on a ghastly greenish hue, spotted with blue. The idea occurred to Cooper-Hewitt, the inventor of the commercial form of the lamp, to make use of the fluorescence of rhodamine to supply the missing red rays. He devised a white reflector coated with a film of celluloid stained with the dye, which, when mounted above the arc, glowed with a bright vermilion colour, adding its rays to those of the lamp, and producing an illumination not very different from daylight. This reflector he called a "light transformer." The efficiency of such a screen is much greater if the fluorescent film is formed on white paper or card than if it is deposited on a silver or tin reflector, in which case the fluorescence is surprisingly feeble. The cause of this was investigated (R. W. Wood, *Phil. Mag.*, 1913) and found to result from the circumstance that the fluorescent light was imprisoned by total reflection in the case of the metal backing, whereas it was at once released by the diffusing surface of the paper.

Both fluorescence and phosphorescence have been utilized in recent years for the production of spectacular effects on a darkened stage illuminated by the powerful ultra-violet lamps, developed during the war by R. W. Wood and described in the *Journal de Physique* (1919). The lamp consists of a mercury arc (in a quartz tube), the light from which is filtered through glass coloured black with a carefully chosen amount of oxide of nickel. The ultra-violet radiations given out by such a lamp are so intense that the entire company in a large auditorium can be rendered fluorescent, fabrics shining with unusual colours, teeth and eyes glowing with a brilliant bluish light (false-teeth appear coal black) and practically everything in the room giving off light of a greater or less intensity. The lens of the eye is also fluorescent under the illumination, and this light falls upon the entire surface of the retina, producing a curious illusion; the room appears to be filled with a bluish haze or smoke, which vanishes the instant the hand is held between the eye and the lamp. These lamps have had a wide application in other fields, such as the diagnosis of certain diseases in which the fluorescence of the tissues are examined in the dark by the ultra-violet radiations, the detection

of adulterants in drugs and chemicals, the differentiation of cotton from silk in fabrics, the comparison of old paintings with recent copies, and so on.

Photographs showing some of these curious effects are reproduced (Plate II, figs. 6, 7 and 8). Fig. 6 is a photograph of a white china plate in front of a journal. A slip of white writing paper, on which invisible writing has been printed with a solution of anthracene, is pasted across the plate. The fluorescence of these objects under ultra-violet illumination is shown by fig. 7. The white plate appears coal black, while the white paper is quite luminous, though not nearly as bright as the letters in anthracene. Fig. 8 is a photograph of a young woman, and shows the fluorescence of the lens (pupil) of the eye. The skin appears as dark as that of a mulatto, while the teeth are very brilliant.

The excitation of fluorescence or phosphorescence by the X-rays is utilized in the screens or fluoroscopes used for visual observations of the internal organs or bones. One very early application of phosphorescence was in the preparation of a paint which glowed in the dark; this so-called Balmain's luminous paint had a considerable vogue during the latter half of the 19th century. It was a calcium sulphide containing certain impurities on which its phosphorescence depended, and after exposure to a strong light remained luminous in the dark for some time. It was used for painting key-holes, gas and electric fixtures, and other objects which had to be located in the dark. It has been supplanted by the modern phosphorescent paints used on watch and clock dials, the luminosity of which is continually excited by a small content of radium. "Canary" glass, coloured by oxide of uranium, is used in the arts and owes its peculiar green luminosity to fluorescence, its colour by transmitted light being a pale yellow. The powerful fluorescence of extremely dilute solutions of an alkaline salt of fluorescein (uranine) has resulted in its employment for tracing possible seepage from drainage systems to springs or wells, a small quantity of the substance thrown into the drain causing the water in the well to show a green fluorescence if seepage occurs.

See R. W. Wood, *Physical Optics* (2nd ed., 1911); E. C. C. Baly, *Spectroscopy* (4th ed., 1927); P. Prigshelm, *Fluoreszenz und Phosphoreszenz* (1928). (R. W. W.)

FLUORINE, a gaseous chemical element of the halogen group having a greenish-yellow colour and a choking smell (symbol F, atomic number 9, atomic weight 19.00). It is never found in the uncombined condition, but in combination with calcium as fluorspar CaF_2 , it is widely distributed; it is also found in cryolite Na_3AlF_6 , in fluor-apatite, $\text{CaF}_2 \cdot 3\text{Ca}_3\text{P}_2\text{O}_8$, and in minute traces in sea-water, in some mineral springs, and as a constituent of the enamel of the teeth. It was first isolated by H. Moissan in 1886 by the electrolysis of pure anhydrous hydrofluoric acid containing dissolved potassium fluoride. The U-shaped electrolytic vessel and the electrodes are made of an alloy of platinum-iridium, the limbs of the tube being closed by stoppers made of fluorspar, and fitted with two lateral exit tubes for carrying off the gases evolved. Whilst the electrolysis is proceeding, the apparatus is kept at a constant temperature of -23°C . by means of liquid methyl chloride. The fluorine, which is liberated as a gas at the anode, is passed through a well-cooled platinum vessel in order to free it from any acid fumes that may be carried over, and finally through two platinum tubes containing sodium fluoride to remove the last traces of hydrofluoric acid; it is then collected in a platinum tube closed with fluorspar plates. Fluorine possesses a specific gravity of 1.265 (H. Moissan); it has been liquefied, the liquid also being of a yellow colour and boiling at -187°C . It is the most active of all the chemical elements; in contact with hydrogen, combination takes place between the two gases with explosive violence, even in the dark, and at as low a temperature as -253°C .; finely divided carbon burns in the gas, forming carbon tetrafluoride; water is decomposed even at ordinary temperatures, with the formation of hydrofluoric acid and "oxygenized" oxygen; iodine, sulphur and phosphorus melt and then inflame in the gas; from chlorides it liberates chlorine, with which it does not combine, but it combines with most metals instantaneously to form fluorides. Organic compounds are rapidly

attacked by the gas.

Only one compound of hydrogen and fluorine is known, namely *hydrogen fluoride* or *hydrofluoric acid*, HF or H_2F_2 , which was first obtained by C. Scheele in 1771 by decomposing fluorspar with concentrated sulphuric acid, a method still used for the commercial preparation of the aqueous solution of the acid, the mixture being distilled from leaden retorts and the acid stored in leaden or gutta-percha bottles. The perfectly anhydrous acid is a very volatile colourless liquid and is best obtained, according to G. Gore, by decomposing the double fluoride of hydrogen and potassium at a red heat in a platinum retort fitted with a platinum condenser surrounded by a freezing mixture, and having a platinum receiver luted on. It can also be prepared in the anhydrous condition by passing a current of hydrogen over dry silver fluoride. The pure acid thus obtained is a most dangerous substance to handle, its vapour, even when highly diluted with air, having an exceedingly injurious action on the respiratory organs, whilst inhalation of the pure vapour is followed by death. The anhydrous acid boils at 19.5°C . (H. Moissan) and melts at -92.3°C . (K. Olszewski). It is a non-conductor of electricity (*see* ACIDS). Potassium and sodium readily dissolve in the anhydrous acid with evolution of hydrogen and formation of fluorides. The aqueous solution is strongly acid to litmus and dissolves most metals directly; it is a conductor of electricity, but inferior to hydrochloric acid in this respect. Its most important property is that it rapidly attacks glass, reacting with the silica of the glass to form gaseous silicon fluoride, and consequently it is used for etching. T. E. Thorpe determined the vapour density of hydrofluoric acid at different temperatures, and showed that there is no approach to a definite value below about 88°C ., where it reaches the value 10.29 corresponding to the molecular formula HF; at temperatures below 88°C . the value increases rapidly, showing that the molecule is more complex in its structure. The probable existence of H_2F_2 is cited by T. M. Lowry as an example of the co-ordination of hydrogen, thus: $(\text{HF}_2)\text{H}$. The aqueous solution behaves on concentration similarly to the other halogen acids; E. Deussen found the solution of constant boiling point to contain 43.2% HF and to boil at 110° (750 mm.).

Fluorine oxide (oxygen fluoride), F_2O , according to P. Lebeau and A. Damiens (1927), results as a by-product when fluorine is prepared by the electrolysis of acid potassium fluoride, as in Moissan's method (above). It is less reactive than fluorine and is stable in the presence of water or glass even at high temperatures; it liberates iodine from potassium iodide, and is only sparingly soluble in water, but fairly soluble in alkalis.

The salts of hydrofluoric acid are known as *fluorides* and are easily obtained by the action of the acid on metals or their oxides, hydroxides or carbonates. The fluorides of the alkali metals, of silver, and of most of the heavy metals are soluble in water; those of the alkaline earths are insoluble. In many of these solubility relationships fluorides differ from chlorides, bromides and iodides. A characteristic property of the alkaline fluorides is their power of combining with a molecule of hydrofluoric acid and with the fluorides of the more electro-negative elements to form double fluorides, a behaviour not shown by other metallic halides. Fluorides can be readily detected by their power of etching glass when warmed with sulphuric acid; or by warming them in a glass tube with concentrated sulphuric acid and holding a moistened glass rod in the mouth of the tube, the water apparently gelatinizes owing to the decomposition of the silicon fluoride formed. The atomic weight of fluorine according to Moissan is 19.05, and E. Moles and T. Batuecas, from the vapour density of methyl fluoride, give 19.00. For the introduction of fluorine into the benzene nucleus, *see* DIAZO-COMPOUNDS.

See H. Moissan, *Le Fluor et ses composés* (1900).

FLUORSPAR derives its name from its use in metallurgical operations as a flux (*cf.* Lat. *fluere*, to flow, and its Ger. name *Fluss-spat*). It is the native fluoride of calcium, also called fluorite or fluor, CaF_2 . One of the most interesting characters of fluorspar is its colour. Specimens have been found of all the colours met with in the mineral kingdom. The colours may be divided roughly into the following groups: white to honey

yellow; pale leek green to emerald green; sky blue; green blue to dark violet; light to carmine red. The colour of a given specimen often varies with the way in which light falls on it. Thus many green-blue specimens are green by transmitted light and blue by reflected. This is the phenomenon of fluorescence to which fluorspar gives its name.

Certain coloured varieties of fluorspar when irradiated with white or ultra-violet light glow with a vivid light, which when examined spectroscopically is seen to consist in general of a number of very fine lines. The character of the light emitted depends to a large extent on the particular specimen of fluorspar and to some extent on the quality of the light which is incident on it. A very interesting series of experiments have shown that the lines occurring in this fluorescent spectrum are due to impurities in the crystal consisting chiefly of manganese and the rare-earths. Urbain was able to prepare an artificial fluorspar containing these impurities in proportions such that the fluorescent spectrum of the product was exactly the same as for one of the common natural varieties. He also found that perfectly pure artificial fluorspar did not fluoresce and it seems likely that the same is true of the natural product since many colourless specimens give no fluorescence. Whilst it is fairly clear that the colour of fluorspar is in many cases due to the presence of impurities like the rare-earth metals, which give a well marked fluorescence spectrum, yet there are others which partly owe their colour to the action of radioactive radiations of the β - and γ -type. These radiations are able to cause a great many fluorspars to acquire a green-blue tint, though they hardly ever produce the other colours so common in this mineral. The presence of radioactive material in some fluorspars may be shown directly by the action a crystal will produce on a photographic plate; in other cases the radiations have recorded their presence in the fluorspar by pleochroic haloes surrounding the minute inclusions. It seems certain that the colour of such specimens is largely due to the radioactive radiations.

A theory has been put forward by Doelter that the impurities which give rise to the fluorescence, *i.e.*, the rare-earths, manganese, etc., are present in a highly dispersed condition resembling that of a colloid. This would account for the disappearance of colour on heating in the case of most fluorspars and the change of colour on irradiation with β - and γ -rays, if we may assume the same phenomena to occur in a crystal as occur in colloidal solutions. It has also been suggested that the colouring is due to an organic pigment, as hydrocarbons have been found in many specimens. Carbon monoxide and dioxide, hydrogen, nitrogen and a little oxygen are sometimes also present.

The known facts relating to the colour of fluorspar indicate that it is in all cases due to impurities which may, like the rare earths, give a colour determined by the fluorescence spectra, or produce a colour by scattering action resulting from the fine state of their division.

Fluorescent Light, emitted in the visible spectrum, ceases instantly on cutting off the exciting light but an emission of light in the ultra-violet continues for a long time. This emission has been detected by means of a photographic plate over a period of the order of a month. Associated with this phenomenon is another remarkable property of fluorspar. When heated in the dark, after being exposed to the light, it emits a bright light of colour varying with the specimen and the temperature. The crystals begin to glow at temperatures ranging between 40° – 80°C . and continue for some hours if not heated too strongly. After they have ceased glowing they do not on cooling emit any more ultra-violet light. There is no adequate theory to account for these phenomena, which are probably also due to impurities since they do not occur with all specimens.

The crystal habit of fluorspar is generally cubic: in addition the forms (111), (110), (311), (211), (210), (310), (421) are often found. The habit appears to depend very much on the mode of origin: fluorspar formed hydrothermally is generally simple cubic, but when formed more rapidly in pneumatolytic processes it is frequently octahedral and rich in faces. Twin crystals are not uncommon, two cubes interpenetrating so that

they are symmetrically arranged about a face of the octahedron. Fluorspar has a hardness of 4, so that it is scratched by a knife though not so readily as calcite. Its specific gravity is about 3.2. The structure consists of two interpenetrating cubic lattices one of calcium and one of fluorine. The former is face-centred with the unit cell of length 5.45 Å.U. The simple-cubic lattice of fluorine atoms has a unit cell of half this length and is placed so that each fluorine atom is at the centre of a tetrahedron formed of calcium atoms.

Fluorspar is widely used in metallurgy as a flux and an electrolyte. On account of its high melting-point it is usually mixed with other fluorides and chlorides, when it is a good solvent for aluminium oxide and metallic silicates. These properties render it particularly suitable for the extraction of aluminium since the impurities in the ore consist largely of silicates. It is also used extensively in the steel industry for the production of ferro-silicon, ferro-manganese and ferro-vanadium, and in lead-smelting. Considerable quantities of the mineral are used in the production of enamel and opal glass and very perfect crystals are employed in the manufacture of apochromatic lenses. It is used as a source of hydrofluoric acid, which it evolves when heated with sulphuric acid. The coloured variety known as Blue John is much worked as an ornamental stone. By impregnation with resin the otherwise brittle spar may be worked on a lathe and very beautiful and delicate work has been done in this way.

The mineral is of very wide distribution. Some of the finest crystals occur in the lead-veins of the Carboniferous limestone series in the north of England, especially at Weardale, Allendale and Alston Moor. It is also found in Aberdeenshire, Cornwall and south Devon. Fine yellow fluorspar occurs in some of the Saxon mines and beautiful rose-red octahedra are found in the Alps near Göschenen. Many localities in the United States yield fluorspar and it is worked commercially in Colorado, Illinois, Kentucky, New Mexico, British Columbia and Guipuzcoa (Spain).

FLUSHING (Dutch *Vlissingen*), in the province of Zeeland, Holland, on the south side of the island of Walcheren, at the mouth of the estuary of the western Scheldt, 4 m. S. by W. of Middelburg, with which it is also connected by tramway and canal. Pop. (1927) 21,742. An important naval station and fortress up to 1867, Flushing has since become a packet station. In 1872 the railway was opened which, in conjunction with the boat service to England (Queenborough and Harwich), forms one of the main routes between England and the Continent. In 1873 the harbour, docks and canal works were completed. Yet the navigation of the port remains far behind that of Rotterdam or Antwerp. As a summer resort Flushing has acquired considerable popularity. It possesses a town hall, containing a collection of local antiquities, a theatre, an exchange, an academy of sciences and a school of navigation. The Jakobskerk, founded in 1328, contains monuments to de Ruyter (1607–76) and Jacob Bellamy (1757–86). The chief industries of the town are connected with the ship-building yards and packet service. The chief imports are colonial produce and wine, wood and coal. The exports include agricultural produce, shrimps and meat.

FLUSHING, formerly a township and a village of Queens county, N.Y., U.S.A., on Long Island, at the head of Flushing bay, since 1898 a part of the borough of Queens, New York city. It was settled in 1644 by a company of English nonconformists who had probably been living at Flushing in Holland, from which the new place took its name. Subsequently a large number of Quakers settled here, and in 1672 George Fox spent some time in the township. Before the Revolutionary War Flushing was the country seat of many rich New Yorkers and colonial officials.

FLUTE, in music, is a general term applied to wood-wind instruments consisting of a pipe pierced with lateral holes and blown directly through the mouthpiece without the intervention of a reed.

The flute family is classified according to the type of mouth-

piece used, *i.e.*, (1) those with the simple lateral mouth-hole or embouchure which necessitates holding the instrument in a transverse position; (2) those with the whistle or fipple mouthpiece which allows the performer to hold the instrument vertically in front of him; (3) those having no mouthpiece of any sort, in which the column of air is set in vibration by blowing obliquely across the open end of the pipe, as in the ancient Egyptian nay, and the pan-pipe or syrinx (*q.v.*).

Of these the transverse flute has now entirely superseded, not only the obsolete third class, but also the whistle flute, which has

BY COURTESY OF CARL FISCHER, INC.

THE BOEHM FLUTE, MODELLED BY THEOBALD BOEHM

survived only in the so-called penny whistle, in the "flute-work" of the organ (*q.v.*), and in the French flageolet.

The *Transverse Flute* or *German Flute* includes the *concert flute*, known both as flute in C and as flute in D, the piccolo (*q.v.*) or octave flute, and the fife (*q.v.*), and consists of a tube open at one end and nominally closed at the other by means of a plug or cork stopper. Virtually, however, the tube is an open one giving the consecutive harmonic series of the open pipe or of a stretched string.

The compass of the modern flute is three octaves with chromatic semitones from middle C upwards. The sound is produced by holding the flute transversely with the embouchure turned slightly outwards, the lower lip resting on the nearer edge of the embouchure, and blowing obliquely across, not into, the orifice. The flat stream of air from the lips, known as the air-reed, breaks against the sharp outer edge of the embouchure. The current of air, thus set in a flutter, produces in the stationary column of air within the tube a series of pulsations or vibrations caused by the alternate compression and rarefaction of the air and generating sounds of a pitch proportional to the length of the stationary column, which is practically somewhat longer than the length of the tube. The length of this column is varied by opening the lateral finger-holes.

The bore of the early flute with six finger-holes was invariably cylindrical throughout, but towards the end of the 17th century a modification took place, the head joint alone remaining cylindrical while the rest of the bore assumed the form of a cone having its smallest diameter at the open end of the tube. The conical bore greatly improved the quality of tone and the production of the higher harmonics of the third octave. Once the conical bore had been adopted, the term flute was exclusively applied to the new instruments, the smaller flutes, then cylindrical, used in the army being designated fifes (*q.v.*). At the present day in England, France and America, the favourite mode of construction is that introduced by Theobald Boehm, and known as the "cylinder flute with the parabolic head," though the conical type is still usually employed in military bands.

The quality of tone depends somewhat on the material of which the flute is made. Silver and gold produce a liquid tone of exquisite delicacy suitable for solo music, cocus-wood and ebonite, a rich mellow tone of considerable power suitable for orchestral music. The tone differs further in the three registers, the lowest being slightly rough, the medium sweet and elegiac, and the third bird-like and brilliant. The proportions, position and form of the stopper, and of the air chamber situated between it and the embouchure are mainly influential in giving the flute its peculiar slightly hollow timbre, due to the paucity of the upper partials of which, according to Helmholtz, only the octave and twelfth are heard.

The technical capabilities of the flute are practically unlimited to a good player who can obtain sustained notes diminuendo and crescendo, diatonic and chromatic scales and arpeggios both legato and staccato, leaps, turn, shakes, etc., with the greatest facility.

Instruments of the flute type appear to be of very ancient origin. The Hindus, Chinese and Japanese all claim to have had

them from time immemorial, the like applying to the Egyptians, and also to the Greeks and Romans.

The first essentially western European trace of the transverse flute occurs in a German ms. of the 12th century, the celebrated *Hortus deliciarum* of the abbess Herrad von Landsperg, in which Fol. 221 shows a syren playing upon an instrument of this type, which Herrad explains in a legend as a *tibia*.

According to Quantz, it was in France, and about the middle of the 17th century, that the first modern modifications were introduced in the manufacture of the flute, including the abandonment of the cylindrical bore in favour of a conical one, and the introduction of keys. But no maker had as yet devoted his attention to the rational division of the column of air by means of the lateral holes, and it was left for Theobald Boehm, a Bavarian maker, to embody this and many other improvements in the completely remodelled instruments which he brought out in 1832 and in 1846.

The old English *fipple flute* or *flute à bec* is described under the headings RECORDER and FLAGEOLET. (X.)

In architecture flute describes vertical channels or curved sinkages used in a series for decorative purposes, especially when employed upon the shafts of columns. Flutes may be separated from each other by a sharp edge or ridge known as an arris, or by a small, vertical flat surface known as a fillet. The earliest known flutes occur in Egyptian columns, where they are obviously the result of the attempt to decorate simply the piers of a rockcut tomb. If the corners are cut off a square pier, an octagonal pier results; if its corners are in turn cut off, one of 16 sides. Such piers are common in the tombs at Beni Hassan (12th dynasty). In many, the sides are made slightly concave in order to emphasize the vertical lines at the corners. The result is a fluted pier. In the temple at Karnak (c. 1400 B.C.), and that of Queen Hatshepsut, at Deir-el-Bahri (c. 1500 B.C.), similar fluted supports appear. Such piers are sometimes known as Proto-Doric.

Whether borrowed from the Egyptians or developed independently, flutes became universal in Greek Doric building. In early examples they are segmental in plan, but later a section approximating an elliptical curve, or one formed with three centres, was the most common type as such a curve gave greater emphasis to the line of the arris, without too great depth in the flute itself. In columns of the Ionic and Corinthian orders the flutes are separated by fillets and here, more than ever, an elliptical section is necessary, in order to bring the edges of the flute as nearly parallel to a column radius as possible. In general, flutes separated by fillets are deeper than flutes separated by arrises, varying from one quarter of the width, as in the Ionic columns in the cella of the temple at Bassae (c. 450 B.C.), to one half the width, as in the Erechtheum. The number of flutes varies from 16 to 24 in Doric examples, with 20 as the most common number. In Ionic and Corinthian columns, the number of flutes is usually greater, averaging 24, but in the archaic temple of Artemis at Ephesus (c. 500 B.C.) there are 52. Similarly in the Persian palace columns of Susa and Persepolis, obviously influenced by Greek work, the number of flutes is great, varying from 30 to 52. Roman columns mostly followed Greek precedent, but with less refinement and a general substitution of semicircular and segmented flutes, in place of the refined Greek ellipses. In some of the smaller Roman examples, particularly in domestic work, the lower portions of the flutes are filled either with a convex moulding known as reeding or by merely filling them to a flat surface in an effort to preserve the arrises and fillets from damage. Twisted, helical or spiral flutes are found occasionally in Roman work, are frequent in mediaeval Italy and were spasmodically used during the high Renaissance and Baroque, as in Sammichele's Bevilacqua palace at Verona (1530). Except where there was direct imitation of Roman work, as in much of the Romanesque of Burgundy and Provence, fluting was not used in mediaeval work outside of Italy.

Flutes are frequently used to decorate horizontal bands, espe-

cially the coronas, or flat projecting portions of the Corinthian cornice, and also in friezes, as in much English and American late Georgian work. Fountain basins and sarcophagi are also often fluted, in many cases with flutes not vertical, but taking an S curve. Fluting occurs in mediaeval work only in styles where there was much imitation of Roman work, as the Romanesque of Burgundy and Provence. (T. F. H.)

FLUX, in metallurgy, a substance introduced in the smelting of ores to promote fluidity, and to remove objectionable impurities in the form of a slag. The substances in commonest use are:—lime or limestone, to slag off silica and silicates, fluorspar for lead, calcium and barium sulphates and calcium phosphate, and silica for removing basic substances such as limestone. Other substances are also used, but more commonly in assaying than in metallurgy. Sodium and potassium carbonates are valuable for fluxing off silica; mixed with potassium nitrate, sodium carbonate forms a valuable oxidizing fusion mixture; "black flux" is a reducing flux composed of finely divided carbon and potassium carbonate, and formed by deflagrating a mixture of argol with quarter to half its weight of nitre. Borax is very frequently employed; it melts to a clear liquid and dissolves silica and many metallic oxides. Potassium bisulphate is useful in the preliminary treatment of refractory aluminous ores. Litharge and red lead are used in silver and gold assays, acting as solvents for silica and any metallic oxides present. The word is derived from Lat. *fluxus*, a flowing, and retains this meaning in medicine, etc.

FLUXIONS, a form of the calculus (*q.v.*) developed by Sir Isaac Newton (*q.v.*), beginning in 1665. The word *fluxion*, as used by him, denoted the rate at which a variable (flowing quantity, fluent) increases or decreases at a given instant of time. If x and y were taken to be the flowing quantities (fluents) $y=x^2$, then it could be shown that $\dot{y}=3x^2\dot{x}$. In the alternative differential notation we should have $dy=3x^2dx$. (See CALCULUS.)

FLY, a name given to the winged stage of many insects such as butterfly (see LEPIDOPTERA), dragon-fly (*q.v.*), may-fly (*q.v.*), caddis-fly (*q.v.*), etc.; also specially used by entomologists to mean any species of two-winged flies or DIPTERA (*q.v.*). In ordinary parlance *fly* is often used in the sense of the house-fly (*q.v.*), and by colonists and sportsmen in Africa with reference to the tsetse-fly (*q.v.*).

Out of doors the flies that most commonly come under notice are the daddy-long-legs or crane-fly (*Tipula*), the wasp-like or bee-like hover-flies (fam. *Syrphidae*), the horse-flies and their allies (fam. *Tabanidae*), and various others. Apart from the house-fly proper (*Musca domestica*), several species are commonly found in houses, e.g., *Stomoxys calcitrans*, the biting house-fly or stable-fly, *Pollemia rudis* or cluster-fly, blue-bottles or blow-flies of the genus *Calliphora*, *Lucilia* or green-bottles, *Sarcophaga carnaria* or flesh-fly, and several others.

FLY-CATCHER, the name for birds of the family *Muscicapidae*, the best known of which is the spotted flycatcher (*Muscicapa grisola*), a summer visitor to most of Europe. It is a small grey bird, fond of perching on railings or posts, whence, ever and anon, it darts to snap up some passing insects. The call note is plaintive. It builds a neat nest among the twigs which sprout from the bole of a tree, in a hole in a wall and similar places. It lays four to six pale greenish-blue eggs, freckled with rust-colour.

The pied flycatcher (*M. atricapilla*) is more of a woodland bird and is less common. It has an agreeable song, and the plumage of the cock is black and white. Other species of this genus occur in Europe, Asia and Africa.

The paradise flycatchers (*Tchitrea*) are distinguished by the long tail-feathers and, usually, white plumage of the male. They are found in the forests of Africa and tropical Asia. The fantailed flycatchers (*Rhipidura*) are Australian; they have the curious habit of turning over in the air, like a tumbler pigeon. Several other genera inhabit Africa and Australia.

The name "flycatcher" is also used for other insectivorous birds; e.g., certain of the *Tyrannidae* (see KINGBIRD).

FLYGARE-CARLÉN, EMILIE (1807-1892), Swedish novelist, was born in Strömstad on Aug. 8, 1807. Her father, Rutger Smith, was a retired sea-captain, and she often accompa-

FLUTE

nied him on the voyages he made along the coast. She married in 1827 a doctor named Axel Flygare, and went with him to live in the province of Småland. After his death in 1833 she returned to her old home and published in 1838 her first novel, *Waldemar Klein*. In the next year she removed to Stockholm, and married, in 1841, the jurist and poet, Johan Gabriel Carlén (1814-75). The most famous of her 31 volumes of tales are *Rosen på Tistelön* (1842; Eng. trans. *The Rose of Tistelön*, 1842); *Enslingen på Johannesskär* (1846; Eng. trans. *The Hermit*, 4 vols., 1853); and *Ett Köpemanshus i skärgården* (1859; *The Merchant's House on the Cliffs*). Fru Carlén published in 1878 *Minnen af svenskt författarlif 1840-1860*, and in 1887-88 three volumes of *Efterskörd från en 80-årigs författarbana*, containing her last tales. Her home was a meeting place for Swedish men of letters. She died at Stockholm on Feb. 5, 1892.

FLYING, COMMERCIAL: see AVIATION, CIVIL; TRANSPORT BY AIR; AERONAUTICS.

FLYING BRIDGE, a type of ferryboat propelled by the resistance of a rope or chain attached to a fixed buoy acting against the forces of the stream. The rudder is fixed obliquely which causes the boat to move at right angles towards the buoy. See also FERRYBOAT.

FLYING BUTTRESS, in architecture, a term given to an arched strut which transmits the thrust of an arch or vault across an open space, such as a side aisle or chapel, to an independent, vertical buttress built in the line of the outer wall of the space. Certain late Roman buttresses, as in the Baths of Diocletian (305) are pierced by arches and are, therefore, in essence, flying buttresses. It was, however, only towards the middle of the 12th century that the structural and aesthetic possibilities of the flying buttresses were understood; their development from then on became one of the important features of Gothic architecture (*q.v.*). The typical Gothic flying buttress consists of a half arch abutting, at its apex, against the nave wall and at the outer end against the vertical mass of the buttress proper, which was frequently weighted by a heavy pinnacle. Where the nave wall was of great height, two, or even three, half arches, one over the other, form the flying buttress.

FLYING CORPS: see AIR FORCES.

"FLYING DUTCHMAN," a spectre-ship popularly believed to haunt the waters around the Cape of Good Hope. Its appearance is considered by sailors as ominous of disaster. The commonest legend declares that the captain of the vessel, Vanderdecken, was condemned for his blasphemy to sail round the cape for ever, unable to "make" a port. The legend was used by Wagner in his opera *Der fliegende Holländer*.

The German legend makes one Herr von Falkenberg the hero and alleges that he is condemned to sail for ever round the North Sea, in a ship without helm or steersman, playing at dice for his soul with the devil.

FLYING FISH, the name generally given to fishes of the genus *Exocoetus*, in which the pectoral fins are greatly enlarged. The lower lobe of the caudal fin is very long and, with strong strokes of the tail, these fishes emerge rapidly from the water and, with the pectoral fins outspread, sail through the air at a great speed, for distances up to 200 yards. It is probable that the flight is an effort to escape from large piscivorous fishes, such as bonitos. There are numerous species of *Exocoetus*, all from warm seas.

The so-called flying gurnards (*Dactylopterus*) are not related to the flying fishes. They have relatively larger pectoral fins than *Exocoetus*, but appear to be less efficient fliers, perhaps because the caudal fin lacks the long lower lobe. There are three or four species from tropical seas.

Pantodon, a little African fresh-water fish, has large pectoral fins and is said to fly; but perhaps the most interesting flier is *Gastropelecus*, a Characin of the rivers of South America, a deep-bodied fish with a large rounded, sharp-edged ventral keel, formed by the greatly expanded coracoid bones, which serve for the attachment of the enormous muscles of the pectoral fins. This fish has been seen by Eigenmann to progress by rapid beats of the strong pectoral fins, with the keel just cutting the surface of the water, and finally to emerge in a true, but not prolonged, flight.

The Catalina flying fish (*Cypsilurus californicus*) of southern California waters, sometimes 18 in. long, one of the largest known species, is a strong flier, with enlarged ventral as well as dorsal fins.

FLYING-FOX or FOX-BAT, the name applied to the fruit-eating bats of the genus *Pteropus*, which contains more than half the family *Pteropidae*. This genus is confined to the tropical regions of the eastern hemisphere and Australia. It comprises numerous species, a considerable proportion of which occur in the islands of the Malay Archipelago. The flying-foxes are the largest of the bats, the kalong of Java (*Pteropus edulis*) measuring about a foot in length, and the wings measuring 5 ft. across. Flying-foxes are gregarious, nocturnal bats, suspending themselves during the day head-downwards from the branches of trees with their wings wrapped about them. They are very good eating, something like hare. Towards evening these bats fly off in companies to the village plantations, where they feed on all kinds of fruit, doing much damage. The flying-fox of India (*P. medius*) is a smaller species, but is found in great numbers wherever fruit is to be had in the Indian peninsula.

FLYING LEMUR: see GALEOPTHECUS.

FLYING-SQUIRREL, the name applied to two very different groups of rodents, in both of which a parachute-like expansion of the skin of the flanks enables them to take long flying leaps from tree to tree.

The first group, allied to the true squirrels, comprises three genera. *Pteromys*, characterized by the extension of the parachute to the interfemoral position, includes the Indian flying squirrel, *P. oral*, a beautifully coloured animal with a loud, screaming voice. *Sciuropterus* has one species extending into E. Europe and another in N. America; otherwise, like the last genus, it is confined to Indo-Malaya; it is distinguished from *Pteromys* by the slight development of the interfemoral membrane and the broad, flat tail. *Eupetaurus* represented by the large *Eu. cinereus* from N. W. Kashmir, is recognized by its tall-crowned molars and long tail, which is twice as long as the body.

The second group is African and consists of certain members of the family *Anomaluridae*, some of which, however, have no parachute. The flying species differ from those of the last group in that the membrane is supported by a bone at the elbow joint instead of by a cartilage at the wrist. There are two flying genera, *Anomalurus* and *Idiurnus*, the latter containing a single small species (*Izenkeri*). They are all similar in habits to the previous group and, like them, are very squirrel-like in appearance.

The term "flying-squirrel" is also applied to certain marsupials but these are more usually called flying-pranglers. (See MARSUPIALIA and GALEOPTHECUS.)

FLY RIVER, a large stream in southern New Guinea, the largest in Papua (British New Guinea). It rises in the Victor Emanuel mountains near the centre of the island and flows first south and then southeast into the Gulf of Papua. It is about 800 m. in length and is navigable with a steam launch for a distance of 535 m. from its mouth. For approximately 100 m. it forms the boundary between British and Dutch New Guinea. The Fly river enters the Gulf of Papua in a great estuary nearly 50 m. across which is filled with a series of low shifting mud islands. The largest, Kiwai, lies in the centre of the estuary and is inhabited. The effect of the tide is felt for a distance of 150 m. up the river, and at the point where it ceases the stream is 600 yd. wide and averages 39 ft. in depth. About 300 m. from its mouth the Strickland river, a tributary as large, and perhaps larger, than the Fly, enters from the north, having its source also in the Victor Emanuel mountains. About 500 m. from the mouth another large tributary, the Alice comes in from the right. Perhaps 550 m. from the mouth the Fly river divides into two nearly equal branches, the one from the left, named the Palmer, being regarded as the tributary. There are no white settlements in the whole vast extent of territory drained by the Fly river, and for the last 400 m. of its course the land is too low and unhealthy for white occupation, though the natives are fairly numerous. The low country is inundated annually. The first hills are found about 480 m. up the river, and from here on nights are cool and the climate healthier. Despite its great navigable length the river is commercially unimportant.

The mouth of the Fly river was discovered by Capt. Blackwood in 1842 and named after one of his ships. It was first explored by Macfarlane and D'Albertis in 1875-76, and in 1877 by D'Albertis alone, who ascended to the entrance of the Alice river. In 1885 Capt. Everill discovered and ascended the Strickland river which D'Albertis had missed. The Alice was not explored until in 1913 by Murray and in 1922 by Austen. In 1927 Champion first made his way to the headwaters of the Palmer river, and Karius crossed to and descended the Strickland river.

See L. M. D'Albertis, *New Guinea* (1880); J. H. P. Murray, *Papua* (1912); W. N. Beaver, *Unexplored New Guinea* (1920) and *The Annual Reports of the Governor-general of Papua*.

FLYSCH, the term long used in geology to denote a peculiar formation occurring specially in the northern Alpine zone. In the Swiss-German dialect it means "slippery earth"; it is applied typically to very thick, light grey shales with intercalations of small beds of ferruginous sandstone and calcareous nodules. When modified by the predominance of calcareous or sandy elements it is usual to refer to "calcareous flysch," "sandy flysch," etc. The flysch extends from south-west Switzerland eastward along the northern Alpine zone to the Vienna basin, whence it may be followed round the northern flanks of the Carpathians into the Balkan peninsula. It is represented in the Pyrenees, the Apennines, the Caucasus and extends into Asia; similar flysch-like deposits are related to the Himalayas as the European formations are to the Alps. The deposits were laid down along the fringes of the great geosynclinal basin (the Tethys) which persisted from Jurassic until late Tertiary times. The flysch is not therefore of the same age throughout; the oldest portions, such as those in the Carpathians, are lower Cretaceous but the greatest development was in upper Eocene (Priabonian or Bartonian) times and lower Oligocene. The absence of fossils from enormous thicknesses of flysch makes the correlation with other formations difficult. Local phases of the flysch have everywhere received special names—such as the Vienna or Carpathian sandstone. Large exotic blocks of granite, gneiss and other crystalline rocks in coarse conglomerates have been variously regarded as indications of glaciation or of coastal conditions. (L. D. S.)

FLYWHEEL. The heavy rim of a flywheel stores up energy and is necessary for two main purposes: (1) to prevent irregular

DIAGRAM OF FLYWHEEL BUILT IN HALVES, WITH LINK JOINT IN RIM
The momentum a flywheel generates ensures the steady running of engines and other machines requiring a sudden reserve of power

running of an engine, (2) to give off a reserve of force with which to overcome sudden resistance. Steam, gas, oil and petrol engines, air-compressors, pumps and some water turbines are concerned with the first-named requirement, and presses, shearing and punching and slotting machines, forging machines, crushers and rolling mills with the second. In engines the pressures transmitted to the crankpins vary, and the flywheel absorbs excess energy, and gives it out again when the pressure is insufficient to meet demands. In explosion types of engines the cyclic variations are very marked, and heavy wheels are necessary to ensure steady running. For single-cylinder internal-combustion engines a specially heavy flywheel is used when driving an electric generator.

The mass of a large flywheel constitutes a potential danger, for if the velocity of the rim exceeds the safe tensile strength of the cast-iron, the wheel will burst and scatter death and

destruction to a considerable distance. The governing device must therefore be infallible, to prevent over-speeding, or "running away." Safety in manufacture is often sought by casting the arms curved instead of straight; as the rim and boss cool in the mould the arms are thus able to accommodate themselves to any pull, nor are they put into a state of stress when all is cold. Large wheels are built up in pieces, for safety and convenience of making and transport; often the rim is cast in several pieces, united with links put in hot, in the recesses, and forming a powerful hold by the act of shrinking. Each arm is separate in the biggest wheels, which are of an enormous weight.

What is termed a *high-speed* flywheel is made of forged steel instead of cast-iron, and goes on a fast-running shaft to give the same result as a much heavier wheel on a slow-speed shaft.

Large wheels are provided with barring gear, consisting either of a lever which is pushed against teeth in the wheel and so starts up the engine, enables it to be moved round for repairs, etc.; or of a sort of hand winch, steam barring engine or electric motor, which serves for large wheels. A flywheel often serves a dual purpose, when its rim takes a driving belt, or when it is grooved for a set of driving ropes. A clutch also may be incorporated, as in automobile practice or in some stamping presses

FOÀ, EDOUARD (1862-1901), French explorer, was born at Marseilles on Dec. 17, 1862. He visited the French colony of Dahomey in 1885, and between 1891 and 1897 made two extended trips into central Africa. On the latter he traversed the continent from the mouth of the Zambesi river on the east coast, through lakes Nyassa and Tanganyika to the Congo valley, ending at Libreville in the French colony of Gabon on the Atlantic Coast. He published *Le Dahomeh* (1895); *Chasses aux grands fauves dans l'Afrique centrale* (1899; Eng. trans. by F. Lees), and *Traversee de l'Afrique du Zambieze au Congo français* (1900).

See *Resultats scientifiques de voyages en Afrique d'Edouard Foà* (1908).

FOA, EUGÉNIE RODRIGUES-GRADIS (1798-1853). French author, was born at Bordeaux in 1798. Separated from her husband while still very young, she earned her living by writing, and became especially noted for her graceful stories for children published largely in the *Journal des enfants* and the *Journal des demoiselles*. Toward the end of her life she became blind. Among her chief romantic writings were *La Juive, histoire du temps de la Regence* (1835); *Les Memoires d'un polichinelle* (1837); *Le Petit Robinson de Paris* (1840); *Le Vieux Paris, Contes historiques* (1840). She died in Paris in 1853.

FOAKES-JACKSON, JOHN FREDERICK (1855-), British church historian, was born at Ipswich on Aug. 10, 1855, and educated at Trinity college, Cambridge (B.A., 1879; M.A., 1882; B.D., 1903). He was ordained by the Bishop of Winchester (1880) and became a lecturer at Jesus College, Cambridge, 1882-1916. He was dean from 1895 to 1916. He was examining chaplain to the Bishop of Peterborough, 1897-1910, Hulsean lecturer in 1902, and Lowell lecturer at Boston, U.S.A., in 1916. After 1916 he was professor of christian institutions at Union Theological Seminary in New York city. His chief publications were *History of the Christian Church to A.D. 337* (1891; 7th ed. to A.D. 461, 1923); *A Biblical History of the Hebrews* (1903; 5th ed., 1924); *Christian Difficulties, a Study of Marcion* (1903); *Biblical History for Schools: Old Testament* (2nd ed., 1927); *Biblical History for Schools: New Testament* (with B. T. D. Smith, 1923); *Introduction to Church History, 590-1314* (1921); *Studies in the Life of the Early Church* (1924); *Principles of Anglicanism* (1924); *Origins of Christianity* (with Kirsopp Lake, 2 vols.); Volume II. of *Outlines of Christianity* (1926); *St. Paul, the Man and the Apostle* (1926).

F.O.B., a contraction for "free on board," an expression used in commerce to denote that a price quoted is inclusive of all costs of carriage and delivering the goods on board the ship or other medium which is to take them to their destination.

FOCA, a town of Bosnia, Yugoslavia. Pop. (1921) 3,459. It is famous for its silver filigree work and inlaid weapons. The soil produces excellent walnuts, but poor tobacco. Lying close

to the frontiers of Novipazar and Montenegro, Foca (*Chocha*) was the scene of almost incessant border warfare during the middle ages. No monuments of this period are left, except the Bogomil cemeteries and the beautiful mosques, which are the most ancient in Bosnia. Foca was a trading station of the Ragusans in the 14th century, if not earlier. In the 16th century it was the residence of the governor of Hercegovina. It was captured by the Montenegrins in the World War.

FOCAL INFECTION, a localized area or pocket in the tissues which affords favourable conditions for germs to grow and produce their poisons and from which these germs and poisons may be absorbed into the blood stream and thence carried to different parts of the body. The most common situations for foci of infection to develop are the tonsils, teeth, the bony cavities of the head or sinuses connecting with the nasal passages, certain of the reproductive organs and less often the intestinal tract, appendix, gall bladder and kidneys.

While germs are the direct cause of focal infections, the development, continuation and especially the harm which comes from their source are often attributable to mechanical factors. This being the case, mechanical treatment or surgery, often becomes necessary to effect a cure. Thus, healing of pockets or abscesses in tonsils is often prevented and bacteria and their products forced into the blood or lymph stream because the narrowed openings of dilated crypts become plugged with the products of infection and the walls are held apart by scar tissue, the result of previous attacks of tonsillitis. Mechanical removal of tonsils such as these, is therefore the only rational procedure. Local antiseptic applications or other forms of treatment can be of little value. Strain or repeated injury from mastication on teeth that are out of proper alinement may be the inciting cause of pyorrhea or infection of the enveloping membrane about the teeth. Since the infection in this condition may extend deep into the tissues along the teeth and form pockets plugged with concretions, cure can best be effected by correcting the contributing mechanical causes.

A properly functioning intestinal tract is rarely a source of infection. If, however, kinks or adhesions develop from localized infection or injury, absorption of bacteria and their poisons is prone to occur. Chronic infections of the appendix and gall bladder which may give rise to disease in distant organs are often directly attributable to kinks, a narrowed lumen from scar tissue or faecal concretions and gall stones. Here again, mechanical or surgical treatment may become necessary.

It has long been recognized that localized infections which are severe and associated with pain, fever and other symptoms, are liable to give rise to disease in remote parts of the body, but that this is also likely to occur from trivial, often symptomless, foci of infection such as occur so commonly in tonsils and in and around teeth, has only recently become apparent. There is still difference of opinion among medical men regarding the relative importance of mild or symptomless focal infections as a cause of diseases in remote parts of the body, but those who have studied the question most thoroughly regard this mode of origin as of common occurrence. Recovery from chronic "rheumatism" even in cases that have perhaps resisted for years the repeated local application of liniments, ointments and other cures is a common occurrence, following the removal of responsible foci. Recurring attacks of arthritis, iritis or other diseases of the eye, appendicitis, ulcer of the stomach, kidney stones and other more vague affections such as slight afternoon rise of temperature, lack of endurance and nervousness, may disappear following the extraction of infected teeth, removal of tonsils, drainage of a sinus or elimination of other responsible focal infection. This new method of treatment is not, however, to be taken as a cure-all. Many conditions be too firmly established to be materially benefited; others are not due to focal infection; or the responsible focus may be hard to locate and may easily be missed.

Foci of infection, besides being directly responsible for many diseases, are prone to have deleterious effects in other ways. They interfere with the cure of diseases not attributable to focal infection, such as syphilis or tuberculosis. They tend to lower the

resistance to intercurrent infections and predispose to complications in acute diseases such as scarlet fever and influenza.

The part played by septic foci in the economy of the human organism has been difficult to ascertain. The germs that lurk in focal infections in persons having widely different diseases are often similar and hence were not considered as possible causes of diseases that were so different in their manifestations. The blood of patients does not usually react in a characteristic way with the bacteria isolated from the diseased tissues or organs. The usual injections in animals are without apparent effect. The germs, when grown on artificial mediums, rapidly lose their peculiar infecting powers. It was not until freshly isolated cultures were injected into the blood stream of animals and the animals, usually seemingly well after injection, were anaesthetized and examined for lesions, that the significance of the germs in foci of infection in their relation to diseases in remote parts of the body, became clearly apparent. These germs, so much alike in appearance, may nevertheless have widely different disease-producing power. Thus, those obtained from foci of infection and the lesions of patients having ulcers of the stomach, produced ulcers of the stomach in the injected animals, or of patients with rheumatism, lesions in the joints, muscles and heart, or if the patient was suffering from certain diseases of the eye, diseases of the eye were prone to occur. Diseases of the heart valves, appendicitis, shingles, inflammation of the gall bladder and gall-stones, diseases of the kidney and of the nervous system, infection of the roots of nails, were produced in large part, with germs from infected teeth or tonsils.

In this field, more than in others, the maxim "An ounce of prevention is worth a pound of cure" holds good. In order, therefore, that the greatest benefits may be derived from this new principle, periodic examinations to learn the state of one's health and the presence or absence of focal infections which may lead to serious disease are strongly indicated. (E. C. R.)

Dental Infection.—The bacteria of the mouth usually produce no perceptible effect elsewhere in the body until they have penetrated within the vascular structures of the teeth and jaw. They reach these structures by invasion of the tooth pulp (erroneously called nerve) through the medium of deep cavities, or by invasion of the gum tissue by pyorrhea.

Pulp infection follows the vascular channels through the root end and sets up an infection in the bone of that region (root abscess). Root abscesses are either acute or chronic. The chronic root-end infection or abscess leads to serious systemic disease. It is usually painless, and the tooth on which it is located may be entirely comfortable and firm when used for mastication, and may show no inflammation of the overlying gum. This fact was responsible for the failure of dentists and medical practitioners to recognize its existence, before the X-ray was adapted to dental use. Then, it was found that teeth infected through cavities and even teeth from which pulps were removed under supposedly aseptic conditions often developed root infections. This led to a sweeping statement by some dental and medical observers that all pulpless teeth eventually become infected, and that all such teeth should be extracted. These propagandists were soon opposed by others, chiefly dentists, and at the present time the dental profession does not condemn the pulpless tooth as such. The question as to whether a given pulpless tooth is infected or not is determined by diagnostic aids, of which the X-ray is the one most widely used, though interpretation of dental radiographs is not always dependable in the absence of local examination.

Foci of infection may also develop around the roots of teeth subject to pyorrhea. In its later stages this infection invades the soft tissue and bone around the roots of the teeth, producing "pus pockets" from which a certain amount of toxic material is absorbed into the circulation. Infectious foci in the jaws may also occur in other ways, e.g., as a result of leaving broken roots in the bone at the time of extraction; again, root abscesses do not always disappear with the extraction of infected teeth, leaving "residual infections" in the jaw; or they may result from third molars (wisdom teeth) which have failed to erupt.

Foci of infection may also occur in the tonsils and in bony

chambers (sinuses) connected with the nose.

A less common, but important, site of focal infection in which pyogenic micro-organisms are concerned, is the appendix. (See DENTISTRY; BACTERIA AND DISEASE.) (J. O. McC.)

FOCH, FERDINAND (1851-1929), French marshal, was born at Tarbes on Oct. 2, 1851. His father's family had long been settled in the south of France, leaving the district of Ariège in the 17th century to establish themselves as woollen manufacturers in the small town of Valentine where they took a prominent part in municipal affairs. On his mother's side, Marshal Foch came of a race of soldiers, his maternal grandfather having been a gallant officer of the Grand Army. His father was a lawyer at Tarbes (Hautes-Pyrénées) who later became a revenue official; and he was frequently transferred from place to place, taking his son with him. The future marshal thus received his education successively at the Lycées at Tarbes and Rodez, the seminary at Polignan and the Jesuit college at St. Étienne.

It was not long before his teachers were struck with his "geometrical mind," and it was decided that he should enter the École Polytechnique, to prepare for which he was sent to St. Clement's College at Metz. After a few months there, however, the war of 1870 interrupted his studies. He enlisted in the infantry but the armistice came before he saw any fighting, and he returned to Metz to finish preparing for his examination. One of his fellow-students has described how, in the midst of a lesson, they learned, on March 11, 1871, by the booming of the German guns, that the treaty of peace had made Metz a city of the German empire. None could foresee that the young student was destined, as marshal, to restore the city to France.

He sat for his examinations at Nancy, which was still occupied by Manteuffel's troops, and was admitted to the École Polytechnique, where he made his mark. In 1873 he was commissioned, and served successively at Fontainebleau, Tarbes and Rennes. He then passed into the École Supérieure de Guerre where, after a tour of duty on the general staff, he was appointed a professor on Oct. 31, 1894. His lectures soon made a sensation, both by the evident soundness of the matter and the originality of the form. Even thus soon his pupils bore witness to the excellent qualities of their professor, who presently became one of the leaders in military doctrine. The lessons given between 1894 and 1900, collected in volumes, constitute the chapters of Foch's great works: *De la conduite de la guerre* and *Des principes de la guerre*, which appeared in 1897 and 1899.

In teaching six batches of staff college students Foch fortified his own military science as well; his years at Paris were, in fact, of capital importance in the higher development of his intellect. When he vacated his post no one doubted that he would return ere long in another capacity. After holding two regimental commands of artillery and spending a year on the staff of the 5th Corps, he was, so to say, imposed on the Government by the opinion of the whole army as the fittest selection for the command of the École de Guerre that he had made famous. It was Clemenceau—at that time prime minister—who made the appointment, giving him the rank of general, and from that day began the cordial relations between the great statesman and the great soldier which were to be revived later under memorable conditions.

The general held his post as head of the École for four years, during which time he threw himself with untiring zeal into the work of this famous centre for military study, giving it a permanent stamp and forming a whole new generation of picked officers. When, in 1911, he was nominated to the command of the 13th Div. at Chaumont, Foch was one of the very few outstanding figures of the army and it was not surprising that, after a brief period in command of the 8th Corps, the wish of everyone acquainted with the higher military personnel brought him to the head of the splendid 20th Corps, stationed about Nancy, which was accounted one of the best elements of the "couverture." Thus, in 1913, he entered, to the sound of trumpets, the town where he had passed his examinations to the tune of the German army fife and whence, before long, he was to march out for the War.

General Foch, who had married Mlle. Julie Bienvenue, had at that time three children—two married daughters and a young son who was destined to be one of the first to fall in the war. Although still attached to his Pyrenean home, the general spent his holidays on a small estate that he had acquired at Trofeunteiou in Brittany. In the summer of 1914 France was so far removed from any idea of attacking Germany that Foch had left Nancy to spend a month in far-away Brittany. A week later events led to his recall and he went into harness.

The Outbreak of War.—He was then a man of 63, but his rare moral, intellectual and physical vigour kept him singularly young. Foch was a man of thought and also, above all, a man of action. Gifted with an intelligence which was never allowed to be idle, ever widening the scope of his knowledge, reflective and delighting—to use his own striking phrase—to "phosphoresce," the great soldier was even stronger in will than in intellect. "Victory = Will. . . . Victory goes always to those who deserve it by the greater force of will. . . . A battle won is a battle in which one will not acknowledge oneself beaten"—these are but a few of the maxims found in his books, in which the word *will* occurs on every page. And in truth, although his grey eyes sparkled with intelligence, the forehead and, even more, the mouth revealed that will which he was able to communicate to all those who came in contact with him in the course of war. It was this will which gave such solidity to his character and protected it from all weaknesses. What is more, it stimulated both conscience and intelligence. He spoke of "these natures, hungry for responsibility, which alone turn out great men," and his own was one of these natures, that no sentimental considerations could either divert or check. For the rest, his clarity of mind translated itself by a realist and somewhat ironic common sense. "What is it about?" was a favourite phrase of his in all circumstances, for he believed in clear vision before direct action.

The 20th Corps formed part of the 2nd Army and Foch was therefore one of the commanders of Castelnau's army, which, on Aug. 19, 1914, was thrown into annexed Lorraine. It will be remembered that this army, after some successes, came up against a formidable resistance in the region of Morhange and failed with heavy losses. Foch had had no part in forming the plan, which met with so cruel a check; he was but one of the executants. He had thrown his army corps resolutely at Morhange and, when repulsed, was still able to organize with perfect coolness its retreat on the solid positions of the Couronne de Nancy. Not content to await the enemy there, he resumed the offensive and, on Aug. 20, threw himself on the German regiments which were waiting to attack in the "gap of Charmes," and in overthrowing them prepared the victory in Lorraine. He was preparing to take his part there when he was called to the Grand Quartier Général, where Joffre entrusted him with the command of an army.

At that time the French were retiring in good order from Belgium and the Ardennes towards the region of the Marne. As a gap tended to open between the 4th and 5th Armies, Joffre gave Foch the mission of forming a new army (the 9th) between them, co-ordinating his action with theirs. He was on the ground before the corps entrusted to him had arrived. In a few days he forged out of them a solid and supple little army which was already well in hand when the celebrated order of Sept. 4 arrested the retreat and prescribed the battle which was to lead to the victory of the Marne.

Foch, after passing the marshes of St. Gond, established himself on the heights which dominate the Petit Morin and of which Fère Champenoise marks the crest. It was thought that his rôle would be limited to supporting Franchet d'Esperey's army on his left. But when the German armies, which, instead of turning the left of the French armies as they had expected, were themselves turned on the right, they tried to penetrate the allied centre precisely in this region of Fère Champenoise and Foch had therefore suddenly to support the main strain of the battle, and that with troops inferior in number. The heights were for a moment carried by the Germans from Mondemont to Fère Champenoise. It was then that, by a clever manoeuvre, Foch rapidly trans-

ferred the 42nd Div. from his left to his centre and thus was able to gain the upper hand and force the enemy back. The extreme fatigue of his troops prevented him from pushing his successes, but he hung on to the retreating Germans and entered Chalons-sur-Marne behind them. His part in the victory of the Marne was capital and it was recognized by a glorious citation in general orders. (*See MARNE, 1ST BATTLE OF.*)

His reputation was so increased after this great crisis that Joffre immediately entrusted him with a new mission—this time one without parallel. Scarcely had the operations of the Marne terminated when, the two armies mutually trying to outflank one another, the "race to the sea" set in from the Oise to the Flemish coast which was only to be closed by the arrival of the Belgian Army and the formation of a continuous front right to Nieuport. The British corps, for their part, had been moved into the region of Ypres, while Joffre detached from the now stable front between the Oise and the Vosges all the forces that he could spare to meet a great attack between the Oise and the sea.

To co-ordinate the action of the heterogeneous troops hurriedly thrown into these regions, a leader of great authority was wanted at once to take the higher direction of the operations of the French armies and to co-operate harmoniously with the Allied armies so as to assure the co-ordination necessary to victory. On Oct. 4, Foch was sent to the Nord to fulfil this mission with the title of "deputy to the commander-in-chief."

He did not limit himself to giving the French armies, from Picardy to Flanders, the most energetic orders but put himself in close and cordial relations with Field-Marshal Sir John French and King Albert I., and established the essential liaison between the Allied armies. Ceaselessly finding the necessary reinforcements and dispatching them to the aid of the hard-pressed British and Belgian corps, he was able by his friendly and generous activity to impose his own resolute ideas and so make himself the soul of the battle of Flanders that, after the fierce fighting of the Yser and of Ypres, ended in mid-November by the definite check of the German invasion for the year 1914. In all this Foch had not merely confirmed his prestige as a strategist, but had won for himself the friendly admiration of his Allies so completely that, even then, it could be foreseen that if, one day, circumstances required unity of command there could be no better choice for it than Foch. Did not Lloyd George say: "He could not have done more for us had he been one of our own generals."

Foch was left therefore in contact with the British and Belgian corps in the capacity of general commanding the Group of Armies of the North. He held the post for two years and thus presided over the two Artois offensives of May and Sept. 1915 and the battle of the Somme (*q.v.*) in the summer of 1916 which the German attack on Verdun prevented from assuming the amplitude and decisive character that had been intended.

After brilliant initial successes the Somme battle seemed to sink in the autumn mud. The disappointment that it caused led to a movement of dissatisfaction with the higher leaders who had presided over it. Joffre having been relieved of his command, Foch was deprived of his also and relegated to Senlis for a mission of inspection. The story was that he was fatigued. This was hardly the case, but he accepted this semi-disgrace with resignation and his valuable advice was always at the disposal of Gen. Lyautey, who had become minister of war.

When, in May 1917, Gen. Pétain was called to the chief command, he himself suggested to the Government that Foch could be usefully employed in the post of chief of the general staff. Having been sent into Italy on the morrow of Caporetto to establish a much-needed understanding with Gen. Cadorna's headquarters, and having remained in constant and cordial relations with Field-Marshal Haig, there was little doubt that when the time came Foch would appear as the single commander that so many people desired by the end of 1917. When, in March 1918, the Germans launched their first grand offensive and the Allied line threatened to break, the necessity of this command became obvious to everybody. It was at Doullens that Foch, on March 29, received from the representatives of the French and British Governments that mission of higher co-ordination that on April

14 became more precise in the form of the chief command of all the Allied armies fighting in France. Already he had grasped this command with a firm hand. Thanks to the close co-operation of the Allies he stopped the Germans at the gates of Amiens, and thereby brought about the final failure of their attempt to break the Anglo-French front and penetrate to the Channel.

Henceforward his whole energies were directed towards assuring this fruitful co-operation. Thus he brought strong French reinforcements to help the British armies, attacked in March and April, and engaged British and American divisions in the battle of the Aisne in May, thus twice checking German offensives that, for a moment, were triumphant. And when the Germans came to a standstill in the pockets that they had driven into our front, he prepared the counter-offensives which, when the hour struck, were to shake and crumple the German front.

The counter-offensive was on the point of being launched against the flanks of these pockets, from the Aisne to the Marne, when, on July 15, a new German offensive took place (*see MARNE, 2ND BATTLE OF*). This met with a partial check which, as we know, had the effect of deepening the pocket in which Foch intended to grip the enemy. The victorious attack of July 18 on the enemy's flanks forced him to retire and gave the signal for the grand Allied offensives.

Foch was now determined to halt no more. He realized that the German armies were beginning to be exhausted but that if they were to be overthrown, the blows must fall thick and fast. The great offensive of Aug. 8 in the region of the Somme which, as it gradually spread and became more violent, forced the Germans to retire on to the Hindenburg Line, was almost immediately followed by the new offensive against that strong position where French and English vied with each other in valour. Once the line had been forced, Foch launched his famous "directive" of Sept. 3 which was in fact the programme of the general attack. The stages of this semi-concentric attack are well known. It stretched from the Meuse into Flanders and was designed to draw the enemy from all parts back on to the region of the Ardennes where Foch hoped to pin them and grasp them. The "directives," which issued from the headquarters of Bombon (and later, Senlis) are clear, resolute and pitiless. At this point Pétain, Haig and Pershing worked in closest harmony with their French colleague. The directives of Oct. 10 and 19 were followed by successes—hard won and unequal, it is true, but which on Nov. 5 culminated in the general retreat of the beaten and exhausted German armies.

Foch, following them closely, had already prepared an operation on a large scale to make an end of them. While the Germans were to be thrown back into the difficult Ardennes region, a huge group of armies under the orders of Castelnau with Mangin as principal executant, were to attack on the Moselle and the Sarre and, reaching the Rhine, were to bar the line of retreat from the encircled Germans. It was at this point that the Germans asked for the Armistice. On Nov. 8 Foch, who had been engaged in drawing up the conditions for three weeks past, received the German plenipotentiaries at Rethondes and, by his masterful attitude, brought them to accept all conditions on Nov. 11, obtaining with the occupation of the left bank of the Rhine the results which he had expected to gain from the supreme battle.

The career of Foch was not at an end. Europe acclaimed him as the leader who had secured the victory. Marshal of France since Aug. 7, he now became a British field-marshal and later a marshal of Poland. He was elected a member of the *Académie française*, which body, emulating the *Académie des sciences*, gave him a wonderful reception, and at Paris, on July 14, 1919, he passed under the *Arc de triomphe de l'Étoile* at the head of the victorious troops. From New York to London and from Brussels to Warsaw he passed from triumph to triumph. He was not, however, content with a parade rôle, and, as president of the Inter-Allied military commission, he was repeatedly called upon to take measures in support of the action of the Allied Governments. In Jan. 1929 the Marshal was taken ill and after a long wasting illness, he died suddenly on March 20. He lay in state beside the grave of the Unknown Poilu at the Arc de Triomphe,

and was then laid to rest at the Invalides near the tomb of Napoleon. (See WORLD WAR.) (L. M.)

FOCHABERS, burgh of barony and village, Moray, Scotland. Pop. (1921) 1,020. It is delightfully situated on the Spey about 9 m. E. by S. of Elgin, the terminus of a branch of the L.M.S.R. connecting at Orbliston Junction with the main line from Elgin to Keith. The town was rebuilt in its present situation at the end of the 18th century, when its earlier site was required for alterations in the grounds of Gordon castle, in which the old town cross still stands. Adjoining the town stands Gordon castle, chief seat of the duke of Richmond and Gordon, built in the 18th century, but including the tower of the older building.

FOCŞANI, a town of Rumania, capital of the department of Putna; on the river Milcov, which formed the ancient frontier between Moldavia and Walachia. Pop. (1928) 28,000; of whom 6,000 were Jews. The chief buildings are the prefecture, schools, synagogues, and many churches, including those of the Armenians and Protestants. Focşani is a commercial centre of some importance, the chief industries being oil and soap manufacture and tannery. A large wine trade is also carried on, and corn is shipped in lighters to Galatz. The annual fair is held on April 29. The vicinity is rich in iron, copper, coal and petroleum. Near Focşani the Turks suffered a severe defeat from the Austrians and Russians in 1789.

FOCUS (Latin for "hearth" or "fireplace"), a point at which converging rays meet, toward which they are directed, or from which diverging rays are directed; in the latter case it is called the virtual focus (see MICROSCOPE; TELESCOPE; LENS). In geometry the word is used to denote certain points, such as the foci of an ellipse or the focus of a parabola. (See ANALYTIC GEOMETRY; CONIC SECTIONS; ELLIPSE; PARABOLA; HYPERBOLA; and PERSPECTIVE.)

FODDER: see FEEDING STUFFS.

FOERSTER, JOSEF BOHUSLAV (1859–), Czech composer, was born on Dec. 30, 1859, at Dětenice, Bohemia. His father, Josef Foerster (1833–1907), was organist at Prague cathedral from 1887 onwards, and did much for the reformation of Church music in Bohemia. The son held various musical posts in Prague, and married an opera singer, Berta Lanterer. They went to Hamburg in 1893 and Foerster became a professor at the Hamburg conservatorium. At Hamburg the Foerstes formed a close friendship with Gustav Mahler, who engaged Frau Foerster for the Imperial Opera in Vienna in 1903. Foerster taught at the Vienna conservatoire, and, after the revolution of 1918, at Prague. From 1922–23 he was director. Foerster has written music in many forms, some of his most important works being those for mixed chorus and orchestra, of which *Mortuis Fratribus* (1918) is one of the best known. His operas, *Deborah* (1891), *Eve* (1897), *Jessica* (1904), *The Unconquered* (1906), and *The Heart* (1922), are distinguished in turn by psychological depth and much subtle expressiveness. Many of Foerster's works have been directly inspired by episodes in his own life, and as time has passed his music has become more and more spiritual and philosophical in content.

See ZD. Nejedlý, *J. B. Foerster* (Prague, 1909), and J. Bartoš, *J. B. Foerster* (Prague, 1922), both written in Czech.

FOG, defined by Shaw as a "cloud, devoid of structure, formed on land in the layers of air which, though nearly stationary, really move slowly over the ground." (See CLOUD.) The same kind of surface cloud may be found at sea accompanied by light breezes or even by wind of fairly considerable force. In its more intense

forms it occasions considerable delays and is sometimes so thick as to paralyse traffic completely. Viewed from a distance, fog has a definite boundary which is absent in some other forms of obscurity.

Fog, mist and haze are somewhat indiscriminately used in ordinary literature. Mist consists of a surface cloud of minute drops of water suspended in the air, e.g., Scotch mist or Dartmoor mizzle; haze should be reserved for smoke or dust obscuration of the lower atmosphere when the air is dry. (See HARMATTAN.) This distinction is often disregarded in practice, and formerly even the Beaufort weather notation had no separate letter for haze (now indicated by *z*), though fog (*f*) and mist (*m*) had separate letters.

The popular distinction between fog and mist is based rather on obscurity effects than on their meteorological character. The phrase "in a fog" has become proverbial, while the usual compounds for traffic aids are "fog-bell," "fog-horn," when vessels are "fog bound"; cf. "fog-signal" (railway); the word "mist" is seldom used in similar connection. Sailors normally restrict the term to an obscurity of the atmosphere in comparatively calm weather; if the obscurity is produced by strong winds and driving rain the terms employed are "thick" weather or "very thick weather." In the latter case, if passing ships are not sufficiently visible for safe navigation some form of fog-warning becomes a duty.

The *Seaman's Handbook of Meteorology* (Met. Office, No. 215, 1914) contains a series of plates based on over 50,000 observations taken during the 30 years ending 1908, which show the average distribution of a fog and mist in the vicinity of the British Isles. Another set of observations taken at St. Mary's, Scilly Isles (30 years period), gives the relation between wind force and the occurrence of fog and mist.

Wind force (Beaufort scale, <i>q.v.</i>)	0 and 1	2	3	4	5	6	7–12
Number of occasions of fog (47) per 1,000 observations	8	7	9	14	6	3	<1
Number of occasions of mist (84) per 1,000 observations	5	6	11	22	20	12	8

The Meteorological Office, the Admiralty and the Trinity House have adopted a scale of "fog" intensity for the use of observers in estimating and recording grades of obscurity caused by fog or mist.

Scale of Fog Intensity

Name and symbol	On sea	On river
Slight fog or mist (<i>f.1</i>) . . .	Horizon invisible, but lights and landmarks visible at working distances.	Objects indistinct but navigation unimpeded.
Moderate fog (<i>f.2</i> and <i>f.3</i>) . . .	Lights, passing vessels and landmarks generally indistinct under a mile. Fog signals are sounded.	Navigation impeded. Additional caution required.
Thick fog (<i>f.4</i> and <i>f.5</i>) . . .	Ships' lights and vessels invisible at $\frac{1}{2}$ mile or less.	Navigation suspended.

On land during *f.1* although objects are indistinct, road and rail traffic is unaffected; *f.2* demands additional caution for rail traffic; *f.3* and *f.4* cause road and rail traffic to be impeded; and *f.5* results in total disorganization of traffic. Related to this scale is a *scale of visibility* in which 0 stands for dense fog, objects not visible at 50 metres; 1, thick fog, objects invisible at 200 metres; 2, fog, objects invisible at 500 metres; and so on up to 9, excellent visibility, objects visible beyond 50,000 metres. At sea or in the country a fog, as a rule, is white and consists of minute water globules forming a cloud of no great vertical thickness which, though it disperses the sunlight, is fully translucent. In large towns the cloud is intensified by smoke, and some dark fogs may be regarded as entirely the result of smoke. The term "high fog" used to describe the blanket of opaque cloud which results in

almost complete darkness during daytime in certain large towns, though the streets are clear of obscurity, is a convenient though inaccurate use of the word "fog."

The physical processes which produce fogs are complicated. The usual process of cloud formation, namely, the cooling of air consequent on the reduction of pressure during ascent, cannot be applied to these surface-clouds. The only other process hitherto recognized as producing clouds in the atmosphere is the mixing of masses of moist air of different temperatures. The mixing results from a slow motion of the air masses, and this motion is essential to the phenomenon.

Over the sea, fog is usually caused by the cooling of a surface layer of air by contact with the underlying colder water. See Shaw, *Life History of Surface Air Currents* (M.O. Publication 174, 1906, p. 72).

The cooling of the air surface in contact with the sea would, on account of convection, affect only a thin layer, but in addition a churning motion is set up by which the cooling is gradually extended upwards. (See G. I. Taylor, *Scientific Results of the Voyage of the Scotia*, 1913.)

Sea fogs are most prevalent in spring and summer when the air is warming rapidly. Many thousands of observations taken over a period of 15 years (1891-1905) in the English channel give June as the most "foggy" month, followed by April, with November the least "foggy." The observations for mists give June as the highest, followed by May, and with November again as the least misty. Sea fogs of the type described above demand that the movement of the air mass shall be slow and that the mixing shall neither be too violent nor too widespread in order that the whole mass producing the fog shall be cooled below the dew point (*q.v.*). From the conditions of its formation sea fog is likely to be less dense at the mast-head than it is on deck.

Shaw suggests that a sea fog is sometimes formed by the slow passage of cold air over relatively warm water, giving a "steaming-pot" type of fog. In this, the layer in contact with the warm water would be clear and the fog would form aloft where the mixing is more complete. Such "steaming-pot" fogs are, however, rare, for if the existence of a cold current over warm water were a sufficient cause of fog in the same manner that the opposite conditions appear to be, then the distribution of fog in place and time would be much more extensive than it is at present.

The formation of land fog seems to involve even more complicated processes. A certain amount of mistiness may arise from the replacement of cold surface air by a warm current, but this would hardly produce large detached banks of fog. The ordinary autumn evening valley fog results from a combination of: the cooling of the surface layer of air during a calm cloudless evening by earth radiation; the slow natural gravitational trickle of the cooled air towards lower levels; a certain amount of eddy motion to promote mixing; and the supply of water vapour from warm, moist soil or from a relatively warm water surface. In this way wreaths and banks collect in the lowest parts, until extensive and deep valleys become filled with fog. (For a minute description of a Lake District fog see J. B. Cohen [*Q. J. Roy. Met. Soc.*, vol. xxx., p. 211, 1904].)

Hence the circumstances favouring fog formation are (1) a site near the bottom level of a drainage area, (2) cold surface air but no wind, (3) a period of vigorous radiation, (4) warm but moist surface soil.

The persistence of these fog banks is remarkable considering that even the smallest particles of a fog cloud must be continually sinking, and consequently should reach the earth or water and lead to the disappearance of the fog-cloud. In sheltered valleys the constant downward drainage of fresh and colder fog-laden material may displace the lower layers which were clearing, but there are occasions when the extent and persistence of land fog seems too great to be accounted for by such means, *e.g.*, Dec. 1904 when the whole of England south of the Humber was covered with fog for several days.

The very presence of fog, of course, tends to its own preservation for much of the solar heat which would otherwise reach the ground and set up convection from below is reflected from the

upper surface of the fog screen. Again, during thick fog there is a reversal of the normal temperature distribution of the lower layers and the surface air may be much cooler than the air immediately above. This reversal of the normal lapse-rate for temperature confers a special stability on the lower layers; convection is impossible and the lower layers are practically shut off from the other layers of the atmosphere; in addition, in large towns the stagnant air becomes further polluted by dust and smoke and this intensifies the fog.

A typical case of inversion of temperatures was noted during the persistent fog of March 6, 1902, when the minimum temperature recorded on the Victoria Tower (400 ft. high) of the Houses of Parliament was $7\frac{1}{2}^{\circ}$ F higher than the minimum measured in a thermometer screen 4 ft. above the ground. The lowest layers, in such circumstances, may attain very low temperatures. A remarkable example occurred in London on Jan. 28, 1909. The city was under fog all day and the maximum temperature only reached 31° F, whereas Warlingham (Surrey), outside the fog zone, had a temperature of 46° F. It is thus evident that while fog arrests surface cooling by radiation, yet it does not provide a protection for plants against frost. (See DEW.)

The somewhat capricious drifting of fog banks over the sea still awaits satisfactory explanation. Shaw suggests that it may be connected with the electrification of particles, as observations at Kew show high electrical potential during fog, but whether this potential is a cause or a result of the fog has not yet been proved. Shaw has also experimentally demonstrated that if a mass of fog-bearing air could be enclosed and kept still for but a short time then the fog would settle; hence as one essential condition of fog formation is the process of mixing, then the apparently capricious behaviour of fog banks may mean that mixing is still going on in the persistent ones, but is completed in the disappearing ones.

Statistics on the geographical distribution of fog are usually not very satisfactory on account of the uncertainty of the distinction between fog and mist. Nevertheless, certain areas have been well mapped, *e.g.*, the north Atlantic ocean and its various coasts as shown in the monthly meteorological charts of the north Atlantic issued by the Meteorological Office, and in the pilot charts of the north Atlantic of the United States Hydrographic Office. These charts show that ocean fog is most extensive in the spring and summer. By June the fog area has extended from the Great Banks over the ocean to the British Isles, in July it is most intense and by August it has notably diminished, while in November, proverbially a foggy month on land, hardly any ocean fog remains.

The various meteorological aspects of fog and its incidence in certain areas are set out in numerous papers. As far back as 1889 the titles referring to fog, mist and haze in the *Bibliography of Meteorology* (Pt. 2. U.S. Signal Office) numbered 306, and there have been very numerous additions. The fogs of London in particular have long been the subject of inquiry, and reports were prepared by A. Carpenter and R. G. K. Lempfert, based upon observations made between 1901 and 1903, in order to examine the possibility of more precise forecasts of fog. (See *Met. Office Publication*, No. 160.)

The study of the properties of fog is especially important for large towns in consequence of the resultant economic and hygienic effects, but it is difficult to get trustworthy statistics in consequence of the vagueness in the classification of fog. For large towns there is great advantage in using a fog intensity scale such as that given above.

Assuming that the term fog means an obscurity amounting to f_2 or more on the scale, it then becomes possible to determine comparative frequencies between places or for the same place at different periods. From such a comparison Brodie suggests (*Q.J.R. Met. Soc.*, vol. xxxi. p. 15) that in recent years there has been a marked diminution of fog frequency as indicated by the following total number of days of fog for the separate years 1871 to 1908.

1871-1880: 42, 35, 75, 53, 49, 40, 46, 63, 69, 74.

1881-1890: 59, 69, 61, 53, 69, 86, 83, 62, 75, 65.

1891-1900: 69, 68, 31, 51, 48, 43, 48, 47, 56, 13.

1901-1908: 45, 42, 26, 44, 19, 16, 37, 19.

But neither the above statistics, nor later figures, nor common

experience suggests that the atmosphere of London is approaching that of the rural districts as regards transparency. Autographic records still show that the atmosphere in many parts of the metropolis is almost opaque to sunshine strong enough to burn the card of the recorder during the winter months, and any substantial reduction of the obscuring pall will only follow a serious handling of the smoke abatement problem. (See Sir Napier Shaw and J. S. Owens, *The Smoke Problem of Great Cities*, 1925.) In this connection it is interesting to note that there was a marked diminution of the smoke layer over Britain during the fuel shortage which accompanied the labour disputes of 1926.

FOGAZZARO, ANTONIO (1842-1911), Italian novelist and poet, was born at Vicenza on March 25, 1842. He was a pupil of the Abate Zanella, one of the best of the modern Italian poets, whose tender, thoughtful and deeply religious spirit continued to animate his literary productions. He began his literary career with *Miranda*, a poetical romance (1874), followed in 1876 by *Valsolda*, which, republished in 1886 with considerable additions, is perhaps his best poem. To the classic grandeur of Carducci and D'Annunzio's impetuous torrent of melody Fogazzaro opposes a Wordsworthian simplicity and pathos. His novels, *Malombra* (1882), the hero of which, Corrado Silli, is said to reflect his own personality, *Daniele Cortis* (1887), *Misterio del Poeta* (1888), did not gain universal popularity until they were discovered and taken up by French critics in 1896. The demand then became prodigious and a new work, *Piccolo Mondo antico* (1896), which critics far from friendly to Fogazzaro's religious and philosophical ideas pronounced the best Italian novel since *I Promessi Sposi*, went through many editions; it is a tale of the liberation of Lombardy and Venetia. Even greater sensation was caused by his novel *Il Santo* (*The Saint*, 1906), on account of its being treated as unorthodox by the Vatican; and Fogazzaro's sympathy with the Liberal Catholic movement—his own Catholicism being well known—made this novel a centre of discussion in the Roman Catholic world. He is also concerned with ethical and religious problems in the volumes of stories *Fedele, ed altri racconti* (1887) and *Idilli spezzati* (1901), and in his essays: *Discorsi* (1898) and *Ascensioni umane* (1899). He died at Vicenza on March 7, 1911. Many of his works have been translated, but, as their beauty depends so much on atmosphere, they lose in the process.

See E. Donadoni, *Antonio Fogazzaro* (1913); L. Gennari, *Fogazzaro* (1918) and *Ritratto di un poeta, Antonio Fogazzaro* (Bergamo, 1921); F. Crispolti, *Antonio Fogazzaro*; *Discorso Commemorativo* (1911); Gallarati-Scotti, *The Life of Antonio Fogazzaro* (1922).

FOG BOW, a white rainbow, about 40° in radius. It has a reddish outer margin and an inner margin of bluish tinge, but the whole of the middle of the band is uncoloured. It occasionally accompanies fogs (q.v.) and its origin resembles that of the normal rainbow, but the smallness of the water drops (under $\frac{1}{10}$ mm.) causes the colours to be mixed and the resulting band to be nearly white. (See HALO.)

FOGELBERG, BENEDICT (or BENGT) **ERLAND** (1786-1854), Swedish sculptor, was born at Gothenburg on Aug. 8, 1786. His father sent him in 1801 to Stockholm, where he studied at the school of art. He then studied in Paris, first under Pierre Guérin, and afterwards under the sculptor Bosio, for the technical practice of sculpture. In 1820 Fogelberg went to Rome, where the greater part of his remaining years were spent. He died at Trieste on Dec. 22, 1854. The subjects of Fogelberg's earlier works are mostly taken from classic mythology. Of these, "Cupid and Psyche," "A Bather" (1838), "Venus and Cupid" (1839) and "Psyche" (1854) may be mentioned. His "Odin" (1831), "Thor" (1842), and "Balder" (1842), though influenced by Greek art, are of greater interest. His portraits and historical figures, as those of Gustavus Adolphus (1849), of Charles XII. (1851), of Charles XIII. (1852), and of Birger Jarl, the founder of Stockholm (1853), are faithful and dignified works.

See Casimir Leconte, *L'Oeuvre de Fogelberg* (1856).

FOGGIA, a town and episcopal see of Apulia, Italy, capital of the province of Foggia, 243 ft. above sea level, in the centre of the great Apulian plain 201 m. by rail S.E. of Ancona and 123 m. N.E. by E. of Naples. Pop. (1921) town, 61,035; commune,

67,314. The name is perhaps derived from the pits or cellars under the pavement slabs of the open spaces (*foveae*) in which the grain of the neighbourhood is stored. The town is the mediaeval successor of the ancient Arpi, 3 m. to the N.; the Normans, after conquering the district from the Eastern empire, gave it its first importance. The date of the erection of the cathedral is 1172; it retains some fine Norman architecture but was much altered after the earthquake of 1731. Only one single gateway of the palace of the emperor Frederick II. (1223, by Bartolommeo da Foggia) is preserved. Here died his third wife, Isabella, daughter of King John of England. Charles of Anjou died here in 1285. After his son's death, it was a prey to internal dissensions and finally came under Alfonso I. of Aragon, who converted the pastures of the Apulian plain into a royal domain in 1445, and made Foggia the place at which the tax on the sheep was to be paid and the wool to be sold. It is still a great wool market, and the centre of an association (the Ovine Nazionale) for improving the breed of sheep. Foggia is a railway centre, on the main line from Bologna to Brindisi, where this is joined by the line from Benevento and Caserta. There are also branches to Rocchetta S. Antonio (and thence to either Avellino, Potenza, or Gioia del Colle), to Manfredonia and to Lucera.

See R. Caggese, *Foggia e la Capitanata* (Bergamo, Arti Grafiche, 1910) well illustrated; A. Haseloff, *Bauten der Hohenstaufen in Unteritalien*, i. (Leipzig, 1914), 67 sqq.

FOG-SIGNALS are employed for the purpose of guidance or warning when visual marks or signals are obscured by fog or their visibility is materially reduced by atmospheric conditions. Permanent fog-signals intended for the guidance of the mariner are usually established in conjunction with coast and harbour lighthouses and lightships. For warning signals made during fog by vessels under weigh or at anchor see NAVIGATION. Fog-signals are used in railway working to warn engine drivers when the ordinary signals are obscured by fog; these commonly consist of detonators, fixed on the rail, which are exploded as the leading wheel of the engine passes over them (see RAILWAY SIGNALLING).

Coast fog-signals are of three kinds: (a) *Aerial-acoustic*; (b) *Submarine-acoustic*, including submarine bells and oscillators, which are usually established on light-vessels as an auxiliary to an aerial-acoustic signal; and (c) *Wireless* or *Radio-fog-signals*. Aerial-acoustic signals may be divided into three classes; first, those sounded by compressed air, such as sirens, diaphones and reed-horns; secondly, explosive signals, including nitrated-guncotton charges, guns and rockets, the two last now seldom used; and thirdly, bells and gongs. The use of wireless-fog-signals has been largely extended since 1921, when the first permanent coast-signal of this description was established, and they are of great importance to aerial as well as to marine navigation. Aerial-acoustic signals are audible at greatly varying distances and, under certain atmospheric conditions, may be heard at a considerable distance though at the same time wholly inaudible in intervening areas. Wireless and submarine signals, on the other hand, are unaffected by the atmospheric conditions which impair the audibility of aerial sound-signals. (See LIGHTHOUSES.)

(N. G. G.)

FÖHN, a warm, relaxing wind experienced on the northern side of the Alpine range most frequently in winter and early spring. Similar local winds occur elsewhere, e.g., Norway, Greenland and North America. In the last case it is known as the *Chinook* and descends the Rocky mountains to the western prairies, as a warm, dry wind which evaporates a great deal of the winter snow. The föhn approaches the ridge from the south, is cooled during its ascent, and moisture may be condensed from it, giving rain or snow. It descends the northern slope by some process still obscure, during which it becomes warmed and dried, and has important local effects with reference to human activities.

See Hann, *Lehrbuch der Meteorologie*, p. 594; and von Ficker, *Innsbrucker Föhn-Studien* (Wien, 1905).

FÖHR, a German island in the North Sea, belonging to the province of Schleswig-Holstein, and situated off its coast. It comprises an area of 32 sq.m. Föhr, the most fertile of the North Frisian islands, is principally marshland, and comparatively

well wooded. The inhabitants are mainly engaged in the fishing industry, and are known as excellent sailors. It is also a summer resort and the chief town, Wyk, has a population of 2,784.

FOIL. 1. A leaf (from Lat. *folium*); so used in heraldry and in plant names, e.g., the "trefoil" clover, and hence applied to anything resembling a leaf. In architecture, the word appears for the small leaf-like spaces formed by the cusps of tracery in windows or panels, and known, according to the number of such spaces, as "quatrefoil," "cinquefoil," etc. The word is also found in "counterfoil," a leaf of a receipt or cheque book, containing memoranda or a duplicate of the receipt or draft kept by the receiver or drawer as a "counter" or check. "Foil" is particularly used of thin plates of metal, resembling a leaf, not in shape as much as in thinness. In thickness foil comes between "leaf" and "sheet" metal. In jewellery, a foil of silvered sheet copper sometimes known as Dutch foil, is used as a backing for paste gems, or stones of inferior lustre or colour. This is coated with a mixture of isinglass and translucent colour, varying with the stones to be backed, or, if only brilliancy is required, left uncoloured, but highly polished. From this use of "foil," the word comes to mean, in a figurative sense, something which by contrast, or by its own brightness, served to heighten the attractive qualities of something else placed in juxtaposition. The commonest "foil" is that generally known as "tinfoil." The ordinary commercial "tinfoil" usually consists chiefly of lead, and is used for the wrapping of sweetmeats, tobacco or cigarettes. A Japanese variegated foil gives the effect of "damaskeening." Many thin plates of various metals, gold, silver, copper, together with alloys of different metals are soldered together in a particular order, a pattern is hammered into the soldered edges, and the whole is hammered or rolled into a single thin plate, the pattern then appearing in the order in which the various metals were placed.

2. An old hunting term, used of the running back of an animal over its own tracks, to confuse the scent and baffle the hounds (from O. Fr. *foler*, to tread). It is also used in wrestling, of a "throw." Thus comes the common use of the word, in a figurative sense, with reference to both these meanings, of baffling or defeating an adversary, or of parrying an attack.

3. As the name of the weapon used in fencing the word is of doubtful origin.

FOIL-FENCING, the art of attack and defence with the fencing foil, is essentially a conventional art, its characteristic limitation lying in the rule that no hits except those on the body shall be considered good, and not even those unless delivered in strict accordance with certain standard precepts. It requires for its perfect display a combination of artificial circumstances, such as even floors, featherweight weapons, and an unconditional acceptance of a number of traditional conventions. In duelling much of the foil-fencer's special achievement and brilliancy has to be sacrificed in the presence of the brutal fact that thrusts on the face or below the waist *do* count, inasmuch as they may kill, that accidental hits in the arm or leg cannot be disregarded, for they may, and generally do, put a stop to the duel. The fact, however, that in these earnest encounters, all conventions that determine a hit vanish, does not in any way justify the notion, prevalent among many, that a successful hit justifies any method of planting the same, and that the mere discarding of all convention in practical sword-play is sufficient to convert a bad fencer into a dangerous duellist.

Whether in foil-fencing or in the simpler and more cautious operation of the practised duellist the one golden rule remains, that one so quaintly expressed by M. Jourdain's *maître d'armes* in Molière's comedy "*Tout le secret des armes ne consiste qu'en deux choses, à donner et à ne point recevoir.*" The modern motto is "*Toucher et ne pas l'être.*" This is the true reason for the conventionalities of foil-play, the idea of "giving without receiving." In courteous bouts a hit has no real value when it is actually cancelled by a counter or when it is delivered in such a way as to admit of a counter. The experience of ages and the careful consideration of probabilities have given birth to the various make-believes and restrictions that go to make sound foil-play. These restrictions are destined to act in the same direction as the warn-

ing presence of a sharp point instead of a button, and thus as far as possible to prevent those mutual hits (*le coup des deux veuves*) which mar the greater number of assaults.

With reference to actual duelling, it is recognized that it would be foolish to attempt the complex attacks, and the neat but somewhat weak parries of the foil and this had led some to assert that, for its ultimate practical purpose (which logically is

FROM CASTLE, "SCHOOLS AND MASTERS OF FENCE" (BELL & SONS)

THRUST IN LOW QUARTE (QUINTE)
PARRIED BY THE CIRCLE (SEPTIME)

that of duelling) the refined art of the foil is next to useless. Some even maintain that a few weeks' special work in that very restricted play which alone can be considered safe on the field of honour will produce as good a practical swordsman as any who have walked the schools for years. Nothing can be further from the truth. The foil-fencer of standing, who can perform with ease and accuracy all the intricate movements of the assault, and has trained his hand and eye to the lightning speed of the well handled foil must logically prove more than a match for the more purely practical but less trained devotees of the *épée de combat*. All argument aside, foil-fencing is considered the basis, so far as practice is concerned, of all sword play, whether with foil, *épée* or sabre.

There are two recognized schools of foil-fencing, the French and the Italian. The French method, which is now generally adopted everywhere except in Italy, is described in this article, reference being made to the important differences between the two schools.

The Foil.—The foil, called in French "*fleuret*" and in Italian "*fioretto*" from the button on its point, consists of the "blade" and the "handle." The blade, which is of steel and has a quadrangular section, consists of two parts: the blade proper, extending from the guard to the button, and the "tongue," which runs through the handle and is joined to the pommel. The blade proper is divided into the "forte," or thicker half (next the handle), and the "foible" or thinner half. Some authorities divide the blade proper into three parts, the "forte," "middle" and "foible." The handle is comprised of the "guard," the "grip" and the "pommel." The guard is a light piece of metal shaped like the figure 8 (Fr. *lunettes*, spectacles) and backed with a piece of stiff leather of the same shape. The grip, which is grasped by the hand, is a hollow piece of wood, usually wound with twine, through which the tongue of the blade passes. The pommel is a piece of metal, usually pear-shaped, to which the end of the tongue is joined and which forms the extremity of the handle. The blade from guard to button is about 33in. long (No. 5), though a somewhat shorter and lighter blade is generally used by ladies. The handle is about 8in. long and slightly curved downwards.

The Italian foil differs from the French in having the blade a trifle longer and more whippy, and in the form of the handle, which consists of a thin, solid, bell-shaped guard from 4 to 5in. in diameter, a straight grip and a light metal bar joining the grip with the guard, beyond the edge of which it extends slightly on each side. Of late years many Italian masters use French blades and even discard the cross-bar, retaining, however, the bell-guard.

In holding the foil, the thumb is placed on the top or convex surface of the grip (the sides of which are a trifle narrower than the top and bottom), while the palm and fingers grasp the other three sides. This is the position of "supination," or thumb-up. "Pronation" is the reverse position, with the knuckles up. The French lay stress upon holding the foil lightly, the necessary pressure being exerted mostly by the thumb and forefinger, the other fingers being used more to guide the direction of the executed movements. This is in order to give free scope to the *doigté* (fingering), or the faculty of directing the point of the foil by the action of the fingers alone, and includes the possibility of changing the position of the hand on the grip. Thus, in parrying, the end of the thumb is placed within half an inch, or even less, of the guard, while in making a lunge, the foil is held as near the pommel as possible, in order to gain additional length. It

will be seen that *doigté* is impossible with the Italian foil, in holding which the forefinger is firmly interlaced with the crossbar, preventing any movement of the hand. The lightness of grasp inculcated by the French is illustrated by the rule of the celebrated master Lafaugère: "Hold your sword as if you had a little bird in your hand, firmly enough to prevent its escape, yet not so firmly as to crush it." This lightness has for a consequence that a disarmament is not considered of any value in the French school.

Strangely enough, when masks began to be generally worn, and the "fleuret" or foil was invented, fencing practice became gradually even more conventional than before. No one seems to have realized that with masks all conventions could be safely laid aside, and sword-practice might assume all the semblance of reality. Nevertheless it should be clearly recognized that the basis of modern foil-fencing was laid with the small sword alone, in and before the days of Angelo, of Danet and the famous chevalier de St. George who were among the first to adopt the fleuret also. All the illustrious French professors who came after them such as La Boissière the younger, Lafaugère, Jean Louis, Cordelois, Grisier, Bertrand and Robert, were foil players pure and simple, whose reputations were gained before the modern *épée-play* had any recognized status.

Foil-fencing in England.—Under such masters the foil, both prior to the advent of the new school of *épée* play in the last quarter of the 19th century, and side by side with it afterwards, always enjoyed great popularity on the European continent. In England, by the middle of that century fencing with both foil and sabre had fallen into neglect. In the last twenty years of the century a gradual revival set in but it was at that time an esoteric art. Its devotees were mainly men of leisure imbued with the traditions of the sword, who in their travels across Europe met the leading continental swordsmen and at home crossed blades with one another in the privacy of the fencing room: first at Angelo's, later at the old rooms of the London Fencing Club, whose membership was confined to those who had been presented at Court, or at Bertrand's famous rooms in Warwick Street. Curiously enough it was the introduction of the *épée* into England in 1900 that sowed the seeds of that popularity for fencing which has become so marked in recent years, a popularity which embraces all weapons, so that the foil may be said to owe a considerable debt of gratitude to its rival. The foundation of the Amateur Fencing Association in December 1901, with eighteen affiliated Clubs, was not only the sign, but, after its inception, the mainspring of this popular revival. Three years before this, however, in 1898, an event had occurred pregnant with consequences, welcomed by some but deplored by others, to the future of foil-fencing. This was the institution of the Amateur Foil Championship for which the Amateur Gymnastic and Fencing Association, the forerunner of the Amateur Fencing Association, was responsible. *The foil was hereby recognised as a competitive weapon.* The argument as to whether so delicate an art as foil-fencing should be purely academic or should lend itself to competition is too long for an article of this nature. A bout with the foils has aptly been compared to a conversation, the attack, parry, riposte, counter-riposte etc., representing arguments advanced and refuted one after the other. When discussion becomes heated the niceties of dialectics take flight, and when fencers fight rather than fence with the foil, the play loses much of its charm. Many lovers of the foil regarded the institution of the championship with much disfavour. For them the manner of the hit mattered just as much as the hit itself, and they feared that the true art of foil play would be lost in the fierce heat of competition. These fears have to some extent been justified. Composed attacks which best exhibit the beauties of the foil are now rare in competitive assaults. In these days it is the hit that counts and the manner of it not at all. It is upon the sudden lunge, with a simple double or disengage—or at the best a one-two—that the competitor relies for success. There was a time when the Association sought to encourage correct foil-fencing by awarding points for style in the championship competitions, but the rule was difficult to apply and was finally abandoned. In some of the later championships foot work has played quite as important a part as hand, a fact most

distressing to some of the older school of foilists who were taught the art standing upon tea-trays from which the feet were not allowed to stray, and were blindfolded in their earlier lessons, the better to learn the feel of the opponent's blade.

Amateur British foil champions since 1910 have been:—

<i>Men</i>		<i>Women</i>	
1910	R. Montgomerie	Miss J. Johnstone	
1911	E. M. Amphlett	Miss G. Daniell	
1912	P. G. Doyne	Miss G. Daniell	
1913	G. R. Alexander	Miss A. B. Walker	
1914	R. M. P. Willoughby	Miss A. B. Walker	
1920	P. G. Doyne	Miss C. A. Walker	
1921	R. Sutton	Miss G. Daniell	
1922	R. Sutton	Miss Millicent Hall	
1923	Major Stenson Cooke	Miss G. Davis	
1924	Flight-Lieut. F. G. Sherriff	Miss G. Daniell	
1925	Flight-Lieut. F. G. Sherriff	Miss G. Davis

FOIX, COUNTS OF. The counts of Foix were a distinguished French family which flourished from the 11th to the 15th century, and during the 13th and 14th centuries were among the most powerful of the French feudal nobles. Living on the borders of France, having constant intercourse with Navarre, and in frequent communication with England, they were in a position peculiarly favourable to an assertion of independence.

The title of count of Foix was first assumed by Roger, grandson of Roger I., count of Carcassonne (d. 1012), when he inherited the town of Foix and the adjoining lands, which had hitherto formed part of the county of Carcassonne. Dying about 1064, Roger was succeeded by his brother Peter, who died six years later, and was succeeded by his son, Roger II. This count took part in the crusade of 1095, and was afterwards excommunicated by Pope Paschal II. for seizing ecclesiastical property; but subsequently he appeased the anger of the Church by rich donations, and when he died in 1125 he was succeeded in turn by his son, Roger III., and grandson Roger Bernard I. The latter's only son, Raymond Roger, accompanied the French king, Philip Augustus, to Palestine in 1190 and distinguished himself at the capture of Acre. He was afterwards engaged in the wars of the Albigenses, and on being accused of heresy his lands were given to Simon IV., count of Montfort. Raymond Roger, who came to terms with the Church and recovered his estates before his death in 1223, was a patron of the Provençal poets, and counted himself among their number. He was succeeded by his son, Roger Bernard II., called the Great, who assisted Raymond VII., count of Toulouse, and the Albigenses in their resistance to the French kings, was excommunicated on two occasions and died in 1241. His son, Roger IV., who followed, died in 1265, and was succeeded by his son, Roger Bernard III., who, more famous as a poet than as a warrior, was taken prisoner both by Philip III. of France and by Peter III. of Aragon. This count married Marguerite, daughter and heiress of Gaston VII., viscount of Béarn (d. 1290), and this union led to the outbreak of a long feud between the houses of Foix and Armagnac, which was continued by Roger Bernard's son and successor, Gaston I., who became count in 1302, inheriting both Foix and Béarn. Becoming embroiled with the French king, Philip IV., Gaston was imprisoned in Paris; but quickly regaining his freedom he accompanied King Louis X. on an expedition into Flanders in 1315, and died on his return to France in the same year. His eldest son, Gaston II., became reconciled with the house of Armagnac, and died at Seville in 1343, when he was succeeded by his son, Gaston III. (1331-91), surnamed Phoebus on account of his beauty, the most famous member of the family. Like his father he assisted France in her struggle against England, being entrusted with the defence of the frontiers of Gascony; but when the French king, John II., showed a marked preference for the count of Armagnac, Gaston left his service and went to fight against the heathen in Prussia. Returning to France about 1357 he delivered some noble ladies from the attacks of the adherents of the *Jacquerie* at Meaux, and was soon at war with the count of Armagnac. In 1362 the latter was

defeated and compelled to pay a ransom; and peace was made in 1377. Early in 1380 the count was appointed governor of Languedoc, but when Charles VI. became king later in the same year this appointment was cancelled. Refusing, however, to heed the royal command, and supported by the communes of Languedoc, Gaston fought for about two years against John, duke of Berry, who had been chosen as his successor, until, worsted in the combat, he abandoned the struggle and retired to his estates, remaining neutral and independent. Left without legitimate sons, Gaston was easily persuaded to bequeath his lands to King Charles VI., who thus obtained Foix and Béarn when the count died at Orthes in 1391. Gaston was very fond of hunting, but was not without a taste for art and literature. Several beautiful manuscripts are in existence which were executed by his orders, and he himself wrote *Déduits de la chasse des bestes sauvages et des oiseaux de proie*. Froissart, who gives a graphic description of his court and his manner of life, speaks enthusiastically of Gaston, saying: "I never saw none like him of personage, nor of so fair form, nor so well made," and again, "in everything he was so perfect that he cannot be praised too much."

Almost immediately after Gaston's death King Charles VI. granted the county of Foix to Matthew, viscount of Castelbon, a descendant of Count Gaston I. Dying without issue in 1398, Matthew's lands were seized by Archambault, count of Grailly and capta de Buch, the husband of his sister Isabella (d. 1426), who became count of Foix in 1401. Archambault's eldest son, John (c. 1382-1436), who succeeded to his father's lands and titles in 1412, and married Jeanne, daughter of Charles III., king of Navarre, played an important part in the wars of his time, supporting at different periods the kings of Aragon, France and England. The next count was John's son, Gaston IV., who married Leonora (d. 1479), a daughter of John, king of Aragon and Navarre. In 1447 he bought the viscounty of Narbonne, and having assisted King Charles VII. in Guienne, he was made a peer of France in 1458. In 1455 his father-in-law designated him as his successor in Navarre, and Louis XI. of France gave him the counties of Roussillon and Cerdagne, and made him his representative in Languedoc and Guienne; but these marks of favour did not prevent him from joining a league against Louis in 1471. His eldest son, Gaston, the husband of Madeleine, a daughter of Charles VII. of France, died in 1470, and when Gaston IV. died two years later, his lands descended to his grandson, Francis Phoebus (d. 1483), who became king of Navarre in 1479, and was succeeded by his sister Catherine (d. 1517), the wife of Jean d'Albret (d. 1516). Thus the house of Foix-Grailly was merged in that of Albret and subsequently in that of Bourbon; and when Henry of Navarre became king of France in 1589 the lands of the counts of Foix-Grailly became part of the French royal domain.

See Le Père Anselme, *Histoire généalogique*, tome iii. (1726-33); H. Castillon, *Histoire du comté de Foix* (Toulouse, 1852); J. M. de Madaune, *Gaston Phoebus, comte de Foix et souverain de Béarn* (Pau, 1865); Froissart's *Chroniques*, ed. S. Luce and G. Raynaud (1869-97); D. J. Vaissète, *Histoire générale de Languedoc*, tome iv. (1876); and L. Flourac, *Jean Ier, comte de Foix, Vicomte Souverain de Béarn* (1884).

FOIX, PAUL DE (1528-1584), French prelate and diplomatist, was ambassador to England from 1561 to 1565. He was then sent to Venice, and returned a short time afterwards to England to negotiate a marriage between Queen Elizabeth and the duke of Anjou. He fulfilled several important missions during the reign of Henry III. of France. In 1577 he was made archbishop of Toulouse, and in 1579 was appointed ambassador to Rome, where he died on May 15, 1584.

There is some doubt as to the authenticity of *Les Lettres de Messire de Paul de Foix* . . . (1628). See *Gallia Christiana* (1715 seq.); "Lettres de Catherine de Médicis," edited by Hector de la Ferrière (Paris, 1880 seq.) in the *Collection de documents inédits sur l'histoire de France*.

FOIX, a town of south-western France, in the middle ages capital of the counts of Foix, and now capital of the department of Ariège, 51 m. S. of Toulouse, on the Southern railway from that city to Ax. Pop. (1926), 4,455. It stands at the confluence of the Arget with the Ariège. Foix probably owes its origin to an

oratory founded by Charlemagne, which later became an abbey, in which were laid the remains of St. Volusien, archbishop of Tours in the 5th cent. The county of Foix included roughly the eastern part of the modern department of Ariège, i.e., the basin of the Ariège. During the later middle ages it consisted of a number of small lordships subordinate to the counts of Foix, with a share in the government of the district. Protestantism early entered the county, and severe religious struggles ensued. The *états* of the county can be traced back to the 14th century. The old town is dominated by an isolated rock crowned by the castle (12th, 14th and 15th centuries). St. Volusien is a Gothic church (14th cent.). The town is the seat of a prefecture, a court of assizes and a tribunal of first instance, and has a chamber of commerce. Iron-working is carried on.

FOKKER, ANTHONY HERMAN GERARD (1890-), Dutch aeronaut and aeroplane constructor, was born on April 6, 1890, at Kediri, Java. He obtained his international pilot certificate in 1911 and in the following year he established an aeroplane factory at Johannesthal, near Berlin. In 1913 he founded another factory at Schwerin in Mecklenburg and during the World War supplied the German Army with flying material, notably the Fokker bi- and tri-planes. After the War he returned to Holland and established the Fokker Aircraft Works in that country. In 1924 the Atlantic Aircraft Corporation was founded in the United States, Mr. Fokker being a director; and a factory was started at Hasbrouck Heights, New Jersey. Meanwhile he had set up a plant in Madrid, which was already producing machines for the Spanish Government. He devoted much of his time to researches in the field of commercial aircraft development, concentrating especially on monoplanes.

FOLARD, JEAN CHARLES, CHEVALIER DE (1669-1752), French soldier and military author, was born at Avignon on Feb. 13, 1669. His military ardour was first awakened by reading Caesar's *Commentaries*, and he ran away from home and joined the army. He was almost continuously on active service, in Italy, in Flanders, and in 1714 under Charles XII. of Sweden. Charles XII. he regarded as the first captain of all time, and it was at Stockholm that Folard began to formulate his tactical ideas in a commentary on Polybius. On his way back to France he was shipwrecked and lost all his papers, but he set to work at once to write his essays afresh, and in 1724 appeared his *Nouvelles Découvertes sur la guerre dans une dissertation de Polybe*, followed (1727-30) by *Histoire de Polybe traduite par . . . de Thuillier avec un commentaire . . . de M. de Folard, Chevalier de l'Ordre de St. Louis*. Folard spent the remainder of his life in answering the criticisms provoked by the novelty of his theories. He died friendless and in obscurity at Avignon in 1752.

Folard's military writings contain a great number of independent ideas, sometimes valuable and suggestive. The central point of his tactics was his proposed column formation for infantry. Struck by the apparent weakness of the thin line of battle of the time, and arguing from the *ἐμβολον* or *cuneus* of ancient warfare, he desired to substitute the shock of a deep mass of troops for former methods of attack, and further considered that in defence a solid column gave an unshakable stability to the line of battle. Controversy at once centred itself upon the column. Whilst some famous commanders, such as Marshal Saxe and Guido Starhemberg, approved it and put it in practice, the weight of military opinion throughout Europe was opposed to it, and eventually history justified this opposition. Amongst the most discriminating of his critics was Frederick the Great, who caused a *précis* of his work to be made by Colonel von Seers, and wrote a preface expressing his views. The work (like others by Frederick) fell into unauthorized hands, and on its publication (Paris, 1760) under the title *Esprit du Chev. Folard*, created a great impression. Frederick saw that "Folard had buried diamonds in a rubbish heap."

See *Mémoires pour servir à l'histoire de M. le Chevalier de Folard* (Paris and Regensburg, 1753), and for a detailed account of Folard's works and those of his critics and supporters, Max Jähns, *Geschichte der Kriegswissenschaften*, vol. ii. pp. 1478-93 (Munich and Leipzig, 1890); see also C. de Coynart, *Le Chevalier de Folard, 1669-1752* (1914).

FIG. 1.—DIAGRAM ILLUSTRATING THREE FORMS OF FOLDS, WITH GENERAL DESCRIPTIVE TERMS

FOLD, a pleat or bend in a flexible material. The termination “-fold” added to numbers, as hundredfold, is of the same origin (O.Eng. *fealdan*), but fold in the sense of an enclosure for animals and hence applied to a community of worshippers has another root, apparently meaning a planked or boarded enclosure (O.Eng. *falded*).

Folds in Geology.—Fold is the general geological term for a curvature of any degree in the stratified rocks of the earth's crust. The French equivalents are *pli*, *plissement*, *videment*; the German, *Falte*, *Faltung*, *Sattelung*.

With but a few exceptions all sedimentary rocks have been formed from the deposition of material, carried down from land masses, in horizontal or very nearly horizontal sheets. Since the earth's crust has always been in a state of movement in one region or another, the stresses set up are relieved in various ways such as fracture (see **FAULT**), sagging down, buckling up and crumpling. Except then, in comparatively recent strata, one rarely finds the stratified rocks lying in the position in which they were laid down. The sheets are folded and fractured to any

degree, from a condition when they show a hardly perceptible inclination to the horizontal to one when they have been contorted and folded over upon themselves so as to give rise to extremely complicated attitudes. Such curved and folded strata are rarely seen except on a small scale in cliff sections from any one particular view-point: *pari passu* with folding on a large scale denudation has been at work to plane down the land masses formed by such arching of the strata, so that what one observes are more or less highly inclined beds outcropping at the surface in different parts of the folded region, these beds being the truncated limbs of the folds.

In describing folds certain terms are used. Fig. 1 shows diagrammatically a simple system of folding; strata curved upwards into an arch, giving rise to a simple *anticlinal fold* or *anticline*, and curved downwards into a trough, a simple *synclinal fold* or *syncline*. The axis of folding is an imaginary line along the crest or the trough and defines the direction of folding. The axial plane divides the fold symmetrically along its axis; in a simple symmetrical fold it will be vertical, but in an asymmetrical fold it

FIG. 2.—ASYMMETRICAL FORMS

will be inclined and may cease to be a plane, becoming a curved surface. On either side of the fold the inclined strata form the *flanks, limbs or slopes*. The innermost strata or rock mass form the *core*. No fold can have an axis of indefinite length, so that it is found that folds die away longitudinally somewhat after the manner of the rumpling which can be produced with the hand in a small area of a table cloth; though the stresses which give rise

FIG. 3.—PITCHING ANTICLINE AND SYNCLINE

to folding in stratified rocks may find relief in some other fashion than folding beyond the margin of these rocks, and hence a fold may terminate differently. Most folds are therefore somewhat like an inverted feeding trough with tapering ends, and the axis, following the crest, will plunge downwards. The anticline is here said to *pitch* or dip in a certain direction, and the angle of inclination to the horizon of the axis at any point is called the *pitch*.

Folds may assume many forms, simple and complex, symmetrical and asymmetrical. There is the simple anticline (and syncline) where the axial plane is vertical; the asymmetrical form where the axial "plane" is inclined or a curved surface. A *dome* is a special case of the symmetrical anticline: here there is no axis and folding appears to have taken place round a point. The dip of the strata around this point is said to be *quaquaversal* or *periclinal*. The converse of this structure, basin shaped, is called a *centro-clinal* fold. Both these forms are somewhat rare. A *monocline* is a fold with only one limb: it passes generally into a fault. The axial plane may be inclined at any angle, from the case where the asymmetry is hardly perceptible to the case where

FIG. 4.—ISOCLINAL FOLDING

it curves into a horizontal position: if the axial plane is inclined at such an angle that the strata of one limb are reversed, the structure is called an *overfold*, and when one limb is horizontal, a *recumbent* fold. In regions of severe folding, a number of axial planes inclined in the same direction give rise to *isoclinal* folding. On a large scale, the earth's crust may be arched up into a broad anticlinal fold, a *geanticline*, and if numerous subordinate flexures are present this is called an *antiplinorium*. The converse, resulting from depression, is a *geosyncline* and a *synclinorium*. A *fan structure* is a great anticline flanked by one or more asymmetrical folds whose axial planes incline inwards. Over wide areas, but on a smaller individual scale, strata are frequently found to be folded in such a complex and irregular manner that they are said to be *contorted*. Great compression has caused the beds to behave as if they were plastic, since they thin out in the limbs and swell

out in the arches. Not only is this seen in large cliff sections but the same occurs in hand specimens and even in rock slices under the microscope. Constituents of rocks, like pebbles in conglomerates are drawn into lenticular shapes and fossils are distorted.

Origin of Folds.—Folding, implying need for the earth's crust to adjust itself to a diminishing surface, is evidently the result of compression. The most obvious cause of this need is the differential shrinkage of the whole mass of the earth, the hotter interior contracting, in cooling, at a greater rate than the crust which is at a low temperature. However, it is still undecided whether there may not be other agencies of even greater impor-

FIG. 5.—QUAQUAVERSAL FOLD, OR DOME UPLIFT. THE RIGHT FAULT IS IN PROCESS OF DENUDATION

tance to account for the contraction of the crust. Though gently folded and little disturbed strata cover very large areas of the earth's surface, highly folded and contorted rocks are generally found in belts. Thus the later mountain ranges, such as the Alps, the Andes and the Himalayas, are formed of highly folded rocks, and probably represent lines of weakness where crustal stresses have found relief the more easily. (C. B. B.)

FOLENGO, TEOFILO (1491-1544), otherwise known as Marliano Coccajo or Cocajo, one of the principal Italian macaronic poets, was born of noble parentage at Cipada near Mantua on Nov. 8, 1491. At sixteen he entered the monastery of Monte Casino near Brescia, and eighteen months afterwards he became a professed member of the Benedictine order. About 1516 he forsook the monastic life for the society of a well-born young woman named Girolama Dieda, with whom he wandered about Italy, supporting himself by his talent for versification. His first work was the *Merlini Coccaii macaronicon*, telling the adventures of a fictitious hero named Baldus. The coarse buffoonery of this work is often relieved by touches of genuine poetry, as well as by graphic descriptions and acute criticisms of men and manners. His next work was the *Orlandino* (1526) an Italian poem of eight cantos, written in rhymed octaves. It bore on the title-page the pseudonym of Limerno Pitocco (Merlin the Beggar) da Mantova. In the same year Folengo returned to his ecclesiastical obedience; and shortly afterwards wrote his *Chaos del tri per uno*, in which, partly in prose, partly in verse, sometimes in Latin, sometimes in Italian, and sometimes in macaronic, he gives a veiled account of the vicissitudes of his life. About 1533 he wrote in rhymed octaves a life of Christ entitled *L'Umanità del Figliuolo di Dio*; and he is known to have composed, still later, another religious poem upon the creation, fall and restoration of man, and some tragedies. In 1543 he retired to Santa Croce di Campesio, near Bassano; and there he died on Dec. 9, 1544. Folengo is frequently quoted and still more frequently copied by Rabelais. The earlier editions of his *Opus macaronicum* are rare. The edition of 1530 exhibits the text as revised by the author.

See E. Fabbrovich, *Merlin Coccaii, Studio critico con annessa antologia dei maccheroni* (Turin, 1923).

FOLEY, JOHN HENRY (1818-1874), Irish sculptor, was born at Dublin on May 24, 1818. He studied at the schools of the Royal Dublin Society and the Royal Academy, London. He began to exhibit at the Academy in 1840, and in 1844 was commissioned to do the statues of John Hampden and Selden for the Houses of Parliament. He became A.R.A. in 1849, and R.A.

in 1858. He executed many commissions in London and Dublin, and for India. He was responsible for the symbolical group "Asia," as well as the statue of the prince himself, for the Albert Memorial in Hyde Park; and "Stonewall Jackson," in Richmond, Va. The statue of Sir James Outram at Calcutta is probably his masterpiece. He died at Hampstead on Aug. 27, 1874.

See W. Cosmo Monkhouse, *The Works of J. H. Foley* (1875).

FOLEY, SIR THOMAS (1757-1833), British admiral, entered the navy in 1770, and served under Admiral (afterwards Viscount) Keppel and Sir Charles Hardy in the Channel, and with Rodney's squadron was present at the defeat of De Lángara off Cape St. Vincent in 1780, and at the relief of Gibraltar. Still under Rodney's command, he went out to the West Indies, and took his part in the operations which culminated in the victory of April 12, 1782. In the Revolutionary War he was engaged from the first. As flag-captain to Admiral John Gell, and afterwards to Sir Hyde Parker, Foley took part in the siege of Toulon in 1793, the action of Golfe Jouan in 1794, and the two fights off Toulon on April 13 and July 13, 1795. At St. Vincent he was flag-captain to the second in command, and in the following year was sent out in command of the "Goliath" (74), to reinforce Nelson's fleet in the Mediterranean. In the battle of the Nile the "Goliath" led the squadron round the French van, and this manoeuvre contributed not a little to the result of the day. Whether this was done by Foley's own initiative, or intended by Nelson, has been a matter of controversy (see *Journal of the Royal United Service Institution*, 1885, p. 916). His next important service was with Nelson in the Baltic. The "Elephant" carried Nelson's flag at the battle of Copenhagen, and her captain acted as his chief-of-staff. From 1808 to 1815 he commanded in the Downs. Sir Thomas Foley, who rose to be full admiral and G.C.B., died while commanding in chief at Portsmouth in 1833.

See J. B. Herbert, *Life and Services of Sir Thomas Foley* (Cardiff, 1884).

FOLGORE DA SAN GEMINIANO, a 13th century Italian poet, of whose life nothing is known. Some of his anti-Ghibelline political sonnets, and a few of his sonnets on the pleasures of the months and the days of the week, have been translated by D. G. Rossetti and by J. A. Symonds.

See Navone, *Le Rime di Folgore* (Bologna, 1880).

FOLIGNO, a town and episcopal see of Umbria, Italy (anc. *Fulginiae*, *q.v.*), 771 ft. above sea-level, province of Perugia, from which it is 25 m. S.E. by rail. Pop. (1921) 12,188 (town), 32,777 (commune). It lies in a fertile plain, on the Topino, a tributary of the Tiber; it is almost square in shape and is surrounded by walls. Several churches contain paintings by Umbrian masters, notably works by Nicolò di Liberatore (or Nicolò Alunno) (1430-1502), a native of the place, and among them his chief work, a large altar-piece (the predella of which is in the Louvre) in S. Nicolò. The cathedral has a Romanesque south façade of 1133. In the same piazza as the south façade is the Palazzo Trinci, erected in 1395-1407, which has a chapel with frescoes by Ottaviano Nelli of Gubbio (1424). The Trinci also erected the fine castle of S. Eracleo, 2 m. S. of Foligno. Raphael's "Madonna di Foligno," now in the Vatican, was originally painted for the church of S. Anna. The Palazzo Orfini and the Palazzo Deli are two good Renaissance buildings. The abbey of Sassovivo, with its fine Romanesque cloisters (1229) lies 2 m. to the E.

Foligno changed hands often during the 13th century, and was destroyed by Perugia in 1281. From 1305 to 1439 it was governed by the Trinci family as deputies of the Holy See, until owing to the defection of one of them, Corrado II., Pope Eugene IV. sent a force against Foligno, to which the inhabitants opened their gates, and Corrado was beheaded. Until 1860 Foligno belonged to the states of the church. It suffered from a severe earthquake in 1832. Foligno is a station on the main line from Rome (via Orte) to Ancona, and is the junction for Perugia. Wool, flannel and felt are among the manufactures.

Paper is said to have been made at the village of Pale, 3 m. N.E. of Foligno, as early as at Fabriano (*q.v.*). The first edition of the *Divina Commedia* was printed here in 1472.

See M. Faloci Pulignani, *Foligno* (Bergamo, Arti Grafiche, 1907).

FOLIO, a term in bibliography and printing, with reference either to the size of paper employed, or of the book, or to the pagination. In the phrase "in folio" it means a sheet of paper folded once, and thus a book bound up in sheets so folded is a book of the largest size and is known as a "folio" (see BIBLIOGRAPHY). Similarly, "folio" is one of the sizes of paper adapted to be thus folded (see PAPER). In book-keeping the word is used for a page in a ledger on which the credit and debtor account is written; in law-writing, for a fixed number of words in a legal document, used for measurement of the length and for the addition of costs. In Great Britain a "folio" is taken to contain 72 words, except in parliamentary and chancery documents, when the number is 90. In the United States 100 words form a "folio."

FOLIUM: see CURVES, SPECIAL.

FOLK-DANCING. The term folk-dance is of modern origin. Its existence implies a certain complexity of development in the social order, and a distinction based, more or less roughly, on this complexity. In a primitive community the whole body of persons composing it is the "folk," and in the widest sense of the word it might equally be applied to the whole population of a civilized state. In its common application, however, to civilizations of the western type (in such compounds as folk-lore, folk-music, etc.) it is narrowed down to include only those who are mainly outside the currents of urban culture and systematic education, the unlettered or little-lettered inhabitants of village and countryside.

In a community of the lower culture all dancing is of the folk; the need for distinction arises when with social progress art-forms split away, develop a self-conscious technique and become the province of a profession and of the cultured. In a developed civilization we may say that folk-dancing is that dancing which has evolved among the peasantry and is maintained by them in a fluid tradition without the aid of the professional dancer, teacher or artist and is not, at least in the particular form observed, practised in towns, on the stage, or in the ball-room.

Folk-dances may be ranged in two categories: (a) social, danced by all who choose, for their own amusement, at any time; (b) ceremonial and spectacular, danced in connection with seasonal festivals, by special, but not in the ordinary sense professional, performers, and having apparently a magico-religious function.

The precise relation between the social dance and the ceremonial dance is hardly to be decided. To assign, as is sometimes done, a ceremonial or religious origin to social dancing as a whole seems in the state of the evidence dangerous. Though the folk-lore is well aware that the serious ceremony of one stage of development may become the adult amusement of the next, and the children's game of the phase following that, and though there is evidence of borrowing from ceremonial sources for social purposes, it would be incautious in the case of the social dance to forget that the impulse to mere amusement is general and early, and to read symbolism into obvious actions of the body, the natural formations into which a number of dancers may fall, or the patterns they trace.

Seasonal and ceremonial dances may have become little more than a periodic diversion and show, but they bear their own marks, and inferences about origin and function may be drawn by examination of the festivals and concurrent ceremonies with which they are linked, features of the dances themselves, and the attitude towards them persisting, however much meanings may have been forgotten, in the performers and the communities in which they survive.

Though in Europe the folk-dance is rapidly dying, no European nation seems as yet to have lost it entirely. From such records as there are, it would appear that with differences of spirit and detail the folk-dances of the several nations present strong analogies and are parallel in origin and function, but close and accurate investigation has in most cases not been undertaken, and the materials for a detailed survey are not yet available. The folk-dances of England, so far the most thoroughly sifted, may be taken as in some degree illustrative. In England the work of collecting was carried out with great completeness by Cecil J. Sharp, to whom is due the fact that more is known about English

folk-dances in detail, both for dancer and folk-lorist, than about those of any other nation. The English Folk Dance Society, which moved under his direction from its foundation until his death, carries on his work of restoring to the people the fine relics of a nearly dying art which he preserved.

The social dance of England is the country-dance; and it is in this that the distinction between folk-dance and art- or ball-room dance tends to be obscured. Country-dances are danced by country-folk at the present day; but by far the greater number, and the most varied forms come to us in the 17 editions (1650-1728) of Playford's "English Dancing Master," and smaller dance manuals. That the country-dance, as presented by Playford, is of folk origin there is no reasonable doubt, but for Playford it was already a ball-room dance fashionable enough to be worth a publisher's attention, and it continued to be so, until its demise, for fashionable assemblies in the 19th century. Nor do we seem to have any certain evidence to show whether the country-dance of the modern countryman is a direct folk-tradition or a surviving back-flow of fashionable forms from town ball-rooms. The latter is a view sometimes maintained, notably by Thomas Hardy. But the country-dance as a type is undoubtedly of folk-growth and has preserved characteristics of its original form, nor is the technique of the countryman in dancing it a ball-room technique.

The French *contredanse* appears, by the evidence available, to be in name if not altogether in substance, derived from the English country-dance.

The ceremonial and spectacular dances are three: the sword-dance, the morris-dance and the procession. The sword-dance is danced at or near Christmas by teams consisting of men only. It is frequently connected with a play, of which an essential part is a mimic beheadal and resuscitation, the beheadal being present even when the play is absent or has lapsed. It is commonly explained as a ceremonial of imitative magic representing the winter death, and subsequent revival of a vegetation-daemon. At a deeper level there may be an underlying phallic symbolism, but the point needs further investigation for proof or disproof. Sword-dances observed in Germany, France and elsewhere resemble those of England.

Both morris and procession are danced in the spring, the morris by men only and most frequently at Whitsuntide. Both are probably developments of a single type of ceremony. They may be explained with some likelihood as acts of apotropaic magic, the perambulation of parish or district for the expulsion of evils and diseases. The use of sticks and bells, together with the former practice of dancing with blackened faces (to which the name morris, *i.e.*, Moorish, "nigger," seems to be due) would be appropriate to a ceremony of this kind. (E. P. B.)

FOLKESTONE, a municipal borough, seaport and watering-place of Kent, England, within the parliamentary borough of Hythe, 71 m. S.E. by E. of London on the Southern railway. Pop. (1931) 35,890. Folkestone is an important port of the Continental passenger service to Boulogne (30 m.). The older part of the town lies in a small valley which opens steeply to the shore. To the north the town is sheltered by hills of 400 to 500 ft., on several of which, such as Sugarloaf and Castle hills, are ancient earthworks. Along the cliff west of the old town a broad promenade called the Leas, commanding a notable view of the channel, extends westward to Sandgate and is connected by foot-paths and lifts with the shore road and gardens below, where there is also a promenade pier. On this cliff stands the old parish church of St. Mary and St. Eanswith, mainly Early English; the original church, attached to a priory, was founded on the site of a convent established by Eanswith, daughter of Eadbald, king of Kent in 630, the monastery being destroyed at the Dissolution. Folkestone harbour has a deep water pier, which, before the World War, had been lengthened to 1,480 ft., and has berths for eight steamers, with a railway platform and a lighthouse. The area of the inner and outer harbours is a little over 12 ac. The fisheries are important, and in addition to the passenger traffic, a large general trade is carried on. Among institutions may be mentioned the grammar school, founded in 1674, the public library and museum, the corporation technical school and a num-

ber of hospitals and sanatoria, including the Royal Victoria hospital, built in 1889-90 and several times enlarged. William Harvey, discoverer of the circulation of the blood, was a native of Folkestone and is commemorated by a tercentenary memorial on the Leas. Folkestone is a member of the Cinque Port of Dover. It is governed by a mayor, seven aldermen and 24 councillors, and has its own court of Quarter Sessions and police. Shorncliffe military camp and the populous suburb of Cheriton lie to the west of Folkestone. There is a branch railway from Folkestone to Canterbury (Elham valley), while the line to Dover (7 m.) passes through a series of cuttings and tunnels in the chalk cliffs, by way of the Warren (on the east of the town overlooking East Wear bay) and Abbot's and Shakespeare's cliffs. In 1915 a serious landslip in the Warren closed the railway for four years. In 1920 the earl of Radnor presented the Warren and East cliff to the town. The remains of a large Roman villa were excavated near the East cliff in 1924 and the corporation undertook the roofing of a portion of the site.

Folkestone (Folcestan) was among the possessions of Earl Godwine when he was exiled from England; at the time of the Domesday Survey it belonged to Odo, bishop of Bayeux. From early times it was a member of the Cinque Port of Dover, and had to find one out of the 21 ships furnished by that port for the royal service. It shared the privileges of the Cinque Ports, whose liberties were exemplified at the request of the "barons" or freemen of Folkestone by Edward III. in 1330. The corporation, which was prescriptive, was entitled the mayor, jurats and commonalty of Folkestone. In 1629 the inhabitants obtained license to erect a port. By the end of the 18th century the town had become prosperous by the increase of its fishing and shipping trades, and by the middle of the 19th century one of the chief health and pleasure resorts of the south coast. Folkestone was an important embarkation point during the World War and one of the ports refuged to civilians. It is estimated that over 100,000 Belgian refugees passed through the port between Sept. 1914 and March 1915. There were later large numbers of Canadian and American troops stationed at Shorncliffe camp. On May 25, 1917, during an air raid, a bomb fell in a crowded street, killing 33 people.

FOLKLAND (*folcland*). This term occurs three times in Anglo-Saxon documents. In a law of Edward the Elder (c. i. 2) it is contrasted with bookland in a way which shows that these two kinds of tenure formed the two main subdivisions of land-ownership: no one is to deny right to another in respect of folkland or bookland. By a charter of 863, King Aethelbert exchanges five hides of folkland for five hides of bookland which had formerly belonged to a thane, granting the latter for the newly-acquired estates exemption from all fiscal exactions except the threefold public obligation of attending the fyrd and joining in the repair of fortresses and bridges. Evidently folkland was not free from the payment of *gafol* (land tax) and providing quarters for the king's men. In Ealdorman Alfred's will the testator disposes freely of his bookland estates in favour of his sons and his daughter, but to a son who is not considered as legitimate five hides of folkland are left, provided the king consents. It is probable that folkland is meant in two or three cases when Latin documents speak of *terra rei publicae iure possessa*.

Two principal explanations have been given to this term. Allen thought that folkland was the common property of the nation (*folc*), out of which the king could carve dependent tenures for his followers more or less after the fashion of continental *beneficia*. These estates remained subject to the superior ownership of the folk and of the king: they could eventually be taken back by the latter and, in any case, the heir of a holder of folkland had to be confirmed in possession by the king. Kemble and Stubbs, among others, followed Allen's lead.

Another theory was started by Professor Vinogradoff in 1893. It considers folkland as landownership by folkright—at common law, as might be said in modern legal speech. In opposition to it bookland appears as landownership derived from royal privileges. The incidents recorded in the charters characterize folkland as subject to ordinary fiscal burdens and to limitations in respect of testamentary succession. Conversely, "bookland," land held

under a royal charter, was normally free from fiscal dues and could be bequeathed at its holder's will. This view of the matter has been accepted by the chief modern authorities.

Maitland, *Domesday Book and Beyond*, 244 ff. (Cambridge, 1897). (P. VI.)

FOLKLORE. The word was coined by W. J. Thoms in 1846 to denote the traditions, customs and superstitions of the uncultured classes in civilized nations. The meaning of words, however, is prescribed not by definition but by usage, and to-day the scope of folklore includes what was deliberately excluded in the early definition, popular arts and crafts, *i.e.*, the material as well as the intellectual culture of the peasantry. Mainly as the result of the work of the English anthropologists, Tylor, Frazer, and others, who directed attention to the use of the analogies presented by the practices and beliefs of the lower culture to illustrate and explain the superstitions and traditional customs of the European peasantry, no sharp boundary is drawn by English practice between the field of folklore and that of social anthropology. But although it is true that their content overlaps and that one can hardly be explored without assistance from the other, the general implication of usage is towards restricting the province of folklore to the culture of the backward elements in *civilized* societies. The use of the word folktales is less circumscribed and the branch of folklore which is concerned with popular stories, will therefore be considered in a section by itself.

The Study of Folklore.—Interest in the traditions, ballads, stories and superstitions of the common folk is no novelty of recent date. One has only to think of the Caroline antiquaries like John Aubrey whose ms. notes upon the *Remaines of Gentilisme and Judaism* were written in 1687, though first printed in their entirety in 1881, or of the renewed interest in popular poetry in the 18th century as evinced by such works as Bishop Percy's *Reliques of Ancient English Poetry*, an interest which reached its literary zenith under the influence of Sir Walter Scott in the early part of the 19th century. The customs of the folk no less than their songs attracted the attention of the 18th century antiquary. John Brand's *Observations on the Popular Antiquities of the British Isles* was first published in 1777; in the early 19th century Hone's *Everyday Book* (1826) and *Year Book* (1829) deserve mention. But the work of the German brothers Grimm, whose *Kinder- und Hausmärchen* was published in 1812 and *Deutsche Mythologie* in 1835, laid the foundations for a study of folktales and popular superstitions upon a more scientific basis and envisaged its problems from a wider point of view than that of the local antiquarian or literary romantic.

The collections of material from different parts of Europe, which were the fortunate consequence of the example set by the Grimms, revealed that, as Aubrey had already noticed, there were many popular beliefs and practices to which parallels could be found in the records of classical antiquity, and that there was a large stock of tales, customs and beliefs, which was common to all European countries. For a time speculation, which was led astray by a mistaken philological theory and by a belief, now proved erroneous, that the *Vedas* represented a very primitive stage of "Aryan" culture, attempted to derive this common stock from the original ancestors from whom the various peoples who now speak languages belonging to the Indo-European family were thought all to have been descended. A prominent feature of the theories of this school, of which Max Müller was the protagonist, was the view that mythology and folktales were vestigial relics of an allegorical religious literature connected with the worship of natural phenomena. But the work of E. B. Tylor, followed by that of Sir James Frazer, whose *Golden Bough* extended to the lower culture the results of Mannhardt's researches into the agricultural customs of the peasantry of Europe, and made popularly effective by the adroit pen of Andrew Lang, demolished these theories by demonstrating that analogies to these supposed survivals of "Aryan" religion among the European peasantry were

to be found also among primitive peoples in all parts of the world. Popular superstitions in Europe, it was now suggested, were not debased remnants of an elaborate archaic religious system, but vestiges of the stages of culture which the higher strata of civilized society had passed through but had outgrown. The world-wide distribution of similar or identical customs was explained by the hypothesis that the normal reactions of the human mind at similar stages of its development to similar conditions of environment will everywhere produce similar results.

This reasonable view has maintained its position upon the whole, though from time to time challenged by theories of varying plausibility advanced by advocates of varying knowledge and intelligence, that these world-wide similarities are due rather to the diffusion of culture from some single civilization. Some have sought this universal source in a lost continent, *Atlantis*; others look to the Vith Dynasty of Egypt, about the details of whose civilization and its history almost equally little is known for certain.

Of the trend of the study of folklore in recent years two features may be noticed. Firstly its materials have been greatly enriched by the systematic collection and recording of data, particularly in the smaller countries of Europe, where circumstances have been peculiarly favourable. Here the recent very strong revival of national sentiment among the smaller nationalities has supplied an effective stimulus, and the opportunities for collection have been exceptionally rich where the conditions of European civilization have been but recently introduced into what were previously peasant societies. Secondly with greater knowledge the complexity of the material is more adequately appreciated, and a more cautious and more historical approach to its problems is general. The acceptance of Tylor's doctrine of survivals led for a time to an exaggerated emphasis upon similarities, which were sometimes superficial, to the neglect of differences, which were often fundamental. Survivals, it was held, could not be dated; it might therefore be assumed that they belonged uniformly to an infinitely remote antiquity, and since no individual originator could be traced or named, some held that all popular songs, ballads and stories were "collective creations of the folk." How a ballad, or indeed any work of art, could actually be evolved by this committee process was never satisfactorily explained, but the view, which possessed a certain sentimental attraction, received some support from the works of the French school of sociologists, Durkheim and his pupils, who endeavored to interpret the data of folklore and social anthropology in terms of contemporary theories about the psychology of crowds.

The present tendency is to recognize that the survivals of which the material of folklore consists, are not all of equal antiquity. Difficult though it undoubtedly is, the main task of the student is that of analysis and stratification. Many of the general ideas which find expression in popular customs and superstitions are doubtless the product of simple psychological reactions to environment, which are common to human nature in all parts of the world, but an examination of the detailed forms in which they have been given expression, often reveals substantial differences. The distribution and, where possible, the chronological development of these specific forms demand the most careful attention. Only thus can the data be disentangled. For, if much is very old, much is relatively recent. Culture is affected by foreign contacts of all kinds, whether peaceful or warlike, and within a single society, the learning of one generation has a way of becoming the folklore of another. Much that is handed down eventually by oral tradition, perhaps in a debased and distorted form, has its origin in literature. The satisfactory analysis, therefore, of folklore material demands the use of every available instrument, historical, literary and philological, as well as that of comparative analogy. What is quite certain is that in this, as in other fields of scientific enquiry, there is no master key which will unlock all secrets with a single simple formula.

Folk Tales and Popular Stories.—The fields of folklore and social anthropology are not rigidly separated. Thus it is not at all uncommon to find in a scientific monograph upon the social and religious customs of some primitive people, a chapter devoted

to their "folklore." This will usually be found in practice to contain legends, stories, riddles and proverbs. Neither the story-telling faculty nor the ability to give forcible expression to moral and social truths or prejudices in picturesque apothegms are limited to any section of the human race. Though in particular cases a proverb may have been borrowed by one people from another, the generic similarity of many proverbs which have a wide distribution (e.g., "one swallow does not make the summer") may well be due to the coincidence of independent invention.

The problem of stories is more complicated. Popular stories fall into three main categories; myths, legends and stories which are told primarily to provide entertainment. As distinct from these last, myths have a purpose. They are essentially aetiological, or, as Mr. Kipling would say, "*Just-So Stories*." Their object is to explain (1) cosmic phenomena (e.g., how the earth and sky came to be separated); (2) peculiarities of natural history (e.g., why rain follows the cries or activities of certain birds); (3) the origins of human civilization (e.g., through the beneficent action of a culture-hero like Prometheus); or (4) the origin of social or religious custom or the nature and history of objects of worship. It will be obvious that myths which fall into the first three categories are likely to present resemblances which may be explained as coincidences, identical questions having provoked similar replies, whereas the myths of our fourth class are likely to differ as widely as the particular customs or local deities which they seek to explain.

Legend may be said to be distorted history. It contains a nucleus of historical fact the memories of which have been elaborated or distorted by accretions derived from myths or from stories of our third kind. In so far as they are historical the similarities between the legends of different peoples must be due to coincidences of real circumstance; in so far as they are fiction, the similarities will be of the same kind as those of myths or fairy stories from which they have really been borrowed.

The majority of the recorded stories of primitive peoples, with the possible exception of the animal tales to which the African races are peculiarly addicted, fall into the categories of myth or legend, perhaps because disinterested or unmotivated flights of the inventive imagination and fancy, which are rare or rudimentary among savage peoples, are essentially products of a relatively advanced civilization. But the problems presented by stories, which are neither myths nor legends, cannot be restricted to Europe; for there is a large stock both of incidents and of plots which is common to all countries between Iceland and India. Is this to be accounted for by the coincidence of independent invention or by diffusion? Theodore Benfey, whose *Pantschatantra* was published in 1859, maintained that India had provided the great reservoir of stories from which European folktales were derived. In Germany the work of Kohler and in England the writings of Clouston helped to elucidate the debt of Western Europe to oriental story-books, and in France the late Emmanuel Cosquin devoted great learning to the maintenance of the extreme view that all European folktales had their prototypes in India.

If we are unable to accept the Indianist position, we may be grateful for definite gains which these scholars achieved. Firstly, they established the fact that certain kinds of similarity can only be accounted for by diffusion. While it is conceivable and often probable that a general idea or an isolated incident may have occurred independently to story-tellers in different countries, it is to ask too much of coincidence to suppose that the same plot, i.e., an identical series of incidents arranged in the same logical order of interest, could be independently invented more than once. Secondly, they proved that an undoubted influence had been exerted upon the folktales of Europe by the big literary collections of Indian stories, which passed through Persian and Arabic translations to the West. Factors in promoting this influence were the pilgrimage to Jerusalem, the crusades and the mediaeval contacts between eastern and western civilization which were occasioned by the material and intellectual expansion of Islam. In mediaeval Europe translations of oriental story-books like the *History of the Seven Wise Masters* provided entertaining literature for the cultured, and eastern tales were collected in preachers'

handbooks of *exempla*, as they were called, in order to enliven and adorn popular sermons. Popular satire, again, as represented by the *fabliaux* of France and Germany adapted this material to its purpose. It was later used again by the writers of *novelle* who presented it in some cases but little altered (e.g., Straparola and Basile) or in others (e.g., Boccaccio) transmuted by genius into the gold of literature.

Thus from the middle ages onwards there has been constant interchange of stories over the whole area, and there are some, though fewer, instances of a common property which goes back to classical times and even to the 5th century B.C. But it is difficult to believe that Indians have had a monopoly of invention, or that stories have not been spread mainly by exchange. The arguments which postulate a necessarily Indian origin for stories which are recorded only in modern oral tradition in India, are unsound. For there is no guarantee of their antiquity upon Indian soil, and indeed there are other reasons to suppose that many of them have entered India with Islam. Further there exist particular plots, the distribution of the variants of which suggests that they have travelled from West to East, and not from East to West. (See also AMERIND FOLK-LORE and NEGRO FOLK-LORE IN AMERICA.)

BIBLIOGRAPHY.—General survey of the subject in *The Handbook of Folklore* 2nd ed. by C. S. Burne, (1914). A survey of current publications on the folklore of all countries appears from time to time in *Archiv für Religionswissenschaft*. A bibliography of works dealing with proverbs was in 1928 in preparation by the Folklore Society. For the folklore of classical antiquity and its relation to European folklore see bibliography and notes in Halliday, *Greek and Roman Folklore*, (New York, 1927).

For the British Isles see the journal *Folk-Lore* and the volumes of *County Folklore* published by the *Folklore Society*. The same society has in preparation an elaborate edition of Brand's *Observations on the Popular Antiquities of the British Isles*.

For Germany a very complete bibliography will be found in Paul's *Grundriss der Germanische Philologie*. See also the notes in the excellent brief sketch of the subject, Fehrle, *Deutsche Feste und Volksbräuche*, 3rd ed. (1927). For France see the uncompleted work of Sebillot, *Le Folklore de France*, and for Italy and Sicily the works of Giuseppe Pitré. Of the smaller countries Finland has been notably active, and a number of important monographs have been published under the title of *F. F. Communications* by the Academy of Helsinki. The modern Greek material is exceptionally rich. Besides the important journal *Laographia* there are the unfinished but monumental works of the late N. Politis on Traditions (*Παραδόσεις*) and Proverbs (*Προιμια*) entitled *Μελέται ἐπὶ τοῦ βίου τοῦ Ἑλληνικοῦ Λαοῦ*, and the very useful collection of his more important papers published in two volumes *Λαογραφικὰ Σύνμικτα*, Athens. Among the fairly numerous collections of modern Greek songs the standard book remains Passow, *Τραγούδια Ῥωμαϊκά, popularia carmina Graeciae recentioris* (Leipzig, 1860).

As regards folktales, the great dictionary of variants Bolte and Polivka, *Anmerkungen zu den Kinder- und Hausmärchen der Brüder Grimm* is indispensable. Of this the third volume contains a full bibliography.

America.—The folklore of the North American Indian is dealt with by the Bureau of Ethnology, the Smithsonian Institution and the *American Anthropologist*. The *Journal of American Folklore* and the memoirs of the American Folklore Society cover popular literature legends but not material culture. The works of Marius Barbeau on French Canada and of Elsie Crews on the Bahamas deserve special note. In South America much activity is being displayed and the work of the Société des Américanistes—and in particular of G. Rivet is of prominence. (W. R. H.)

FOLK-SONG. Any art if it is to have life must be able to trace its origin to a fundamental human need. Such needs must prompt expression among people even in their most primitive and uncultivated state. To this rule the art of music is no exception; Parry has pointed out that the universal law of evolution demands that we should be able to trace even the most elaborate compositions of Beethoven or Wagner back to some primitive germ. This primitive, spontaneous music has been called "Folk-song," a rather awkward translation of the German word "Volkslied" but nevertheless a word which stands for a very definite fact in the realm of music. It has been said that if we did not know by experience of the existence of folk-song we should have to presuppose it theoretically to account for the art of music.

Fortunately theory is borne out by practice. We find that unlettered and untravelled people have both the desire and the power to express themselves musically and these attempts at musical ex-

pression are not mere clownish nonsense, nor are they, as we are sometimes told, degraded reminiscences of "cultured" music, but are something *sui generis*; moreover, among these spontaneous expressions are to be found melodies which are the most treasured possessions of our art—such melodies as "Searching for Lambs" (England), "Ca' the Yowes" (Scotland), "The Londonderry Air" (Ireland), "Innsbrück Ich musz dich lassen" (Germany), "Magali" (Provence), are ample proof of this, and these are only a few examples out of hundreds.

Moreover, as we have already seen, the folk-song must of necessity bear within it the seed of all the future developments of the art. Such a tune as "The Lady in the Dark," from Playford's *Dancing Master*, exhibits in miniature the same ground plan as many a movement from a Beethoven Symphony: indeed this tune has been described as a "Symphony eight bars long."

Folk-music has, of course, its limitations. To start with, folk-music like all primitive art is an applied art, the vehicle for the declamation of a ballad or the stepping of a dance, and it is, therefore, bounded by the structure of the stanza or the dance-figure. Secondly, folk-music (at all events that of the Teutonic and Latin races) is non-harmonic; there is nothing but the melodic line.

But these limitations have their compensating advantages. A tune which is only eight bars long, and which has to be repeated as often as 20 times to accompany a ballad or a dance, must have certain peculiar qualities if it is not to become wearisome; and we find that the best folk tunes only show their true quality after several repetitions.

Again, the purely melodic character of traditional song gives it a wide range of outline, impossible to melodies which are bound by the progressions of underlying harmonies. Melodies of an harmonic nature are almost always in the major or minor modes, but in folk-song other modes, chiefly the Dorian or Mixolydian, are frequent.

The fact that these modes are also to be found in another great body of purely melodic music, namely the plain-song of the Roman Church, has led to the assumption that "modal" folk-songs must be "ancient," or even derived from mediaeval church music. On the propriety of dubbing a folk-song "ancient" or "modern" more will be said later; as to the supposed derivation from plain-song, surely the simple explanation is that folk-song and plain-song, being purely melodic, are based on the same principles; surely no similarity except that of mode can be traced between such tunes as "Seventeen come Sunday" and "Jesu dulcis memoria."

A further and very important limitation of folk-song must be mentioned, namely that it survives by purely oral tradition. By our hypothesis the inventors and disseminators of folk-music are unlettered, and are therefore unable to stereotype their inventions by means of reading and writing. It is on this that the whole nature of folk-song and all questions of its origin and development depend.

It is sometimes held that the word "folk-song" should be used in what is called a "broad" sense so as to include not only genuinely traditional music, but all those songs of a popular character which are habitually sung by the people of a country. But, in fact, the difference between these two classes of music is a real and scientific one, which is properly recognized by the Germans in their distinction between a "Volkslied" and a "Volksthümlicheslied." What common denominator can be found which will cover, on the one hand, such a song as "Tom Bowling" and, on the other, the "Lazarus" tune in *English Country Songs*? In the one case we can judge the date and even guess at the composer; but who can date a folk-song? Indeed, a folk-song is neither new nor old; it is like a forest tree with its roots deeply buried in the past but which continually puts forth new branches, new leaves, new fruit.

Collectors are often asked by would-be intelligent enquirers as to the age of some folk-song, as if the question of age were either important or relevant. Others (sceptics) suggest that the traditional singer "made it up himself." The answer to this, of course, is that quite possibly he did to some extent "make it up himself," although this in no way adds to, or takes away from, its scientific

or artistic value. It is not the question of age or authorship that is important in a folk-song but that of spontaneity and beauty. When a collector nowadays hears a song sung by a traditional singer he may be pretty sure that, if the singer is a true artist, he will have unconsciously added something of his own to what he sings. A folk-song then is always grafting the new on to the old. This is the answer to the question: "How old is that folk-song?" A folk-song is neither new nor old because it is continually taking on new life; it is an individual flowering on a common stem.

This brings us to the vexed question of the "communal growth" of folk-song; and here it may be pointed out that much useless derision has been wasted over a supposed theory of "communal origin." No one has ever laid it down as an indisputable proposition that folk-song has a communal origin, though even this is not so impossible an idea as some people suppose. No one insists that some individual must have invented every word of our language. Who invented "father" or "plough" or "sun" or any other of the words that belong to primitive life? If we admit communal authorship in our language, is it not even more probable in such an intangible matter as music?

However, it is not necessary to prove the communal origin of folk-song in order to argue in favour of its communal growth. It is well known that when a rumoured fact or story becomes spread about it soon is circulated in various altered forms and this in spite of the fact that everyone who repeats the story is anxious to repeat it correctly. How much more then will a song become altered by oral repetition when each new singer is bound only by his artistic predilections? If he thinks he can improve the song, why should he not do so? If he finds it too difficult why should he not simplify it? Thus a folk-song evolves gradually as it passes through the minds of different men and different generations.

Nor will this gradual change ever be a process of deterioration, because those versions of the tune which are distasteful to others will die a natural death. Here then is a clear case of the survival of the fittest. A tune which has been handed down from father to son through many generations will represent the united imaginations of thousands of men and women through hundreds of years of evolution.

This then is the much discussed "communal growth" theory, and it is borne out by the facts. Collectors know well that numerous variants of the same tune have been found in different parts of the country and, conversely, that tunes have been found which are quite distinct from each other, but at the same time have features that point to a common stock. Thus Grimm's famous apophthegm "a folk-song composes itself" is not, after all, a piece of misty emotionalism but represents the hard common-sense facts of the case.

(R. V. W.)

Cowboy Songs.—The ballad spirit, common to all peoples and particularly active in European nations and their descendants, survived until recent years and under exceptionally friendly conditions in the section of the United States lying west of the Mississippi river. Here a fairly large group of men, almost all of Anglo-Saxon descent, were removed from easy contact not only with printed matter but with entertainment of any sort. Each man spent many hours entirely alone when on night herd or when range riding, engaged frequently in work that absorbed only a part of his attention; and he and his small group, about the chuck wagon or in going up the trail, spent long terms with only such social amusements as they could provide for themselves. Situated thus, the ballad-making instinct revived, with the result that there came into being a considerable body of folk-songs which have been preserved and perpetuated by oral tradition, and have been designated loosely for present purposes *Cowboy Songs*.

These songs are interesting chiefly as human documents, for the light that they throw on the conditions of frontier life, and for their reflection of the old time cattle baron and his crew. The whole cycle of the cowboy's experience—its monotony, its fun, its heroes, its love affairs, its dangers, and the epics of the long drives overland from Texas to Montana—is set forth in the songs made and sung by the men themselves. Further, the

material offers to students of folk literature a picture of folk-songs in the process of manufacture and transmission. In a strict sense the songs of the cowboys are not ballads, yet, in the method of production, preservation and distribution, they show points of kinship to the accepted ballads of the Child collection. For example, the refrain of the ballad form is often present, adapted at times to common cattle cries; there are occasional instances both of simple and incremental repetition; some songs are introduced by the stereotyped "Come all ye." Also, a majority of the songs are without known authorship; some of them bear indication of communal composition, probably around the evening camp fires or the larger gatherings of the general round-ups or in song contests, where the champion of one ranch "sang down" the champion of another ranch by the process of singing a greater number of songs. Some are adaptations of songs already well known, changed to fit a new environment; all, of whatever origin, existed for a number of years in oral literature, each singer feeling the freedom of an author, introducing his personal experiences, amending the phrasing, and giving that breath of real life that is present in true folk-lore.

During the time of their highest popularity these songs were not in print except in an occasional newspaper, but later a few small books, now out of print, appeared containing the words of some of the songs along with original verses by the local poet sponsoring them. The best known of the real cowboy songs were widely distributed over the entire west of America 30 versions of the same song coming into the hands of a single collector from locations as far removed from each other as Idaho, California and Texas. In all, some hundreds of genuine cowboy songs were current among the frontiersmen, springing up as naturally, as unobtrusively, as did the prairie grass; and destined, except for the interest of scholars, to perish as noiselessly and as completely. As might be expected some of the cowboy's best poetic effort was expended on songs not suitable for publication.

FOLLEN, AUGUST (or, as he afterwards called himself, **ADOLF LUDWIG** (1794–1855), German poet, was born at Giessen on Jan. 21, 1794, the son of a district judge. He studied at Giessen and Heidelberg, and after leaving the university edited the Elberfeld *Allgemeine Zeitung*. Suspected of being connected with radical plots, he was imprisoned for two years in Berlin. On his release in 1821 he went to Switzerland, where he lived till his death at Berne on Dec. 26, 1855. Besides a number of minor poems he wrote *Harfengrüsse aus Deutschland und der Schweiz* (1823) and *Malegys und Vivian* (1829), a knightly romance after the fashion of the romantic school. The series of sonnets entitled *An die gottlosen Nichtswüteriche*, aimed at the liberal philosopher Arnold Ruge, started a violent literary quarrel. Follen's best-known work is a collection of German poetry entitled *Bildersaal deutscher Dichtung* (1827).

FOLLEN, KARL (1795–1840), German poet and patriot, brother of A. L. Follen, was born at Romrod, Hesse-Darmstadt, on Sept. 5, 1795. He studied at Giessen, and after a year's service in the army (1814) began the study of jurisprudence, and in 1818 established himself as *Privatdocent* of civil law at Giessen. Suspected of political intrigues, he removed to Jena, and thence, after the assassination of Kotzebue, fled to France. After the political murder of the duc de Berry (Jan. 14, 1820), Follen was regarded as suspect, and took refuge in Switzerland; but the Prussian authorities imperatively demanding his surrender, he sought in 1824 the hospitality of the United States of America. Here he taught German at Harvard in 1825, and in 1830 was appointed professor; but he forfeited his post in 1835 by his anti-slavery agitation, and became Unitarian minister at Lexington, Mass. (1836). He perished at sea on the night of Jan. 13–14, 1840. Follen was the author of several celebrated patriotic

liberal songs. The best is perhaps *Horch auf, ihr Fürsten! Du Volk, horch auf!* It was published in A. L. Follen's collection of patriotic songs, *Freie Stimmen frischer Jugend*.

His wife Elisa Lee (1787–1860) published after his death his lectures and sermons, with a biography written by herself (5 vols., Boston, 1846).

FONBLANQUE, ALBANY WILLIAM (1793–1872), English journalist, was born of a French Huguenot family. His father was an Equity barrister and M.P. for Camelford. Fonblanque began journalistic work in 1812, and attracted attention by the boldness of his opinions and the superiority of his style to the ordinary work of the day. In 1830 he became editor of *The Examiner*, and remained in control till 1847. Fully maintaining the level of political independence set by the Hunts, he inspired the admiration even of his opponents by his wit, and *The Examiner* was the standard of literary merit in the journalistic world. In 1847 he became statistical secretary to the Board of Trade, but continued to contribute to *The Examiner*.

See the *Life and Labours of Albany Fonblanque*, edited by his nephew, Edward Barrington de Fonblanque (1874).

FOND DU LAC, a city of Wisconsin, U.S.A., 60m. N. by W. of Milwaukee, at the south end of Lake Winnebago; the county seat of Fond du Lac county. It is on Federal highways 41 and 151, and is served by the Chicago, Milwaukee, St. Paul and Pacific, the Chicago and North Western, and the Soo Line railways, and by numerous motor bus lines and inter-urban trolley-cars. The population was 23,427 in 1920, and was 26,449 in 1930 by the Federal census. It is division headquarters of two of the railways, which have extensive shops just outside the city limits, employing 1,500 men. There are varied and important manufactures, with an output in 1927 valued at \$17,828,884. The city has a wide trade territory, and is the supply point for the many summer resorts around the lake. At Calvary, a few miles east, is a monastery of the Capuchin order, established about 1870. Fond du Lac was settled about 1835, incorporated as a village in 1847, and chartered as a city in 1852.

FONDI, a town of Lazio, Italy (anc. *Fundi*), province of Rome, 12 m. N.W. of Formia, and 69 m. S. of Rome by rail. Pop. (1911) 8,675 (town), 10,613 (commune). It lies 25 ft. above sea-level, at the north end of a plain surrounded by mountains, which extend to the sea. It occupies the site of the ancient Fundi, a Volscian town, belonging later to *Latium adjectum*, on the Via Appia, still represented by the modern high-road which passes through the centre of the town. It is rectangular in plan, and portions of its walls are preserved. The gate on the north-east still exists, and bears the inscription of three aediles who erected the gate, the towers and the wall. In the neighbourhood are remains of ancient villas, and along the Via Appia still stands an ancient wall of *opus reticulatum*, with an inscription, in large letters, of one Varronianus, the letters being at intervals of 25 ft.

The modern town is still enclosed by the ancient walls. The castle on the south-east side has some 15th-century windows with beautiful tracery. Close by is the Gothic church of S. Pietro (formerly S. Maria), the cathedral until the see was united with that of Gaeta (1818). In the Dominican monastery the cell which St. Thomas Aquinas sometimes occupied is shown.

The ancient city of Fundi in 338 B.C. (or 332) received (with Formiae) limited, and in 188 B.C. full citizenship, because it had always secured the Romans safe passage through its territory. This was strategically important for the Romans, as the military road definitely constructed by Appius Claudius in 312 B.C., still easily traceable by its remains, and in part followed by the high-road, traversed a narrow pass, which could easily be blocked, between Fundi and Formiae. The family of Livia, the consort of Augustus, belonged to Fundi. During the Lombard invasions in 592 Fundi was temporarily abandoned, but it came under papal rule by 754. Pope John VIII. ceded it with its territory to Docibile, duke of Gaeta, but sometimes it appears as an independent countship, though held by members of the Caetani family, who about 1297 returned to it. In 1504 it was given to Prospero Colonna. In 1534 Khair-ed-Din Barbarossa tried to carry off Giulia Gonzaga, countess of Fondi, and sacked the

city. In 1721 it was sold to the Di Sangro family, in which it still remains. Its position as a frontier town between the papal states and the kingdom of Naples, just in the territory of the latter—the Via Appia can easily be blocked either north-west at the actual frontier called Portella or south-east of it—affected it a good deal during the French Revolution and the events which led up to the unification of Italy.

The Lago di Fondi, in the middle of the plain, and the marshes surrounding it, compelled the Via Appia to make a considerable détour. The lake was also known in classical times as *lacus Amyclanus*, from the town of Amyclae or Amunclae, founded, according to legend, by Spartan colonists, and probably destroyed by the Oscans in the 5th century B.C.; the bay was also known as *mare Amunclanum*. The ancient Spelunca (mod. *Sperlonga*) on the coast also belonged to the territory of Fundi. Here was the imperial villa in which Sejanus saved the life of Tiberius, who was almost crushed by a fall of rock. Considerable remains of it, and of the caves from which it took its name, still exist 1 m. S.E. of the modern village. Wine of the *ager Caecubus*, the coast plain round the Lago di Fundi, was praised by Horace. The plain of Fondi is the northernmost point in Italy where the cultivation of oranges and lemons is regularly carried on in modern times.

See T. Ashby, in *English Historical Review*, xix. (1904) 557 seq. for a notice of Italian works on the subject. (T. A.)

FONSAGRADA, a town of north-western Spain, in the province of Lugo; 38 m. E.N.E. of Lugo by road. Pop. (1920) 17,750. Fonsagrada, over 3,000 ft. above sea-level, is the market for the agricultural and dairy produce of the fertile valleys in the surrounding mountains, but its trade is mainly local, owing to the lack of communications beyond the Lugo-Rivadeo road which passes through the town.

FONSECA, MANUEL DEODORO DA (1827–1892), soldier and first president of the United States of Brazil, was born in Alagoas, on Aug. 5, 1827, the third son of a Brazilian army officer. He received his education in the military school at Rio de Janeiro and his military experience at the siege of Montevideo (1864) and in the war against Solano López, dictator of Paraguay (1864–70). His courage gained him distinction, and in rapid succession he became colonel (1869), brigadier-general (1874) and general of division in 1884. Soon afterward he was appointed governor of the province of Rio Grande do Sul and turned his attention to politics, but was soon removed from his position because he used his authority to foster republican sentiments. In 1887 (May 14), with General Pelotas, he signed a manifesto in defence of officers' political rights, which gained him the loyalty of the army and the opprobrium of the government. In Dec. 1888, he was assigned to the command of an army corps in the remote interior. When he returned to the capital in Sept. 1889, conditions were ripe for a republican revolt, and he was prevailed upon to head an armed revolution against the government (Nov. 15, 1889). The troops in the capital sided with the insurgents, and with scarcely any bloodshed the huge empire of Pedro II. collapsed. The army and navy rallied to the new cause, a republic was proclaimed, and on Nov. 17 the emperor and his family were banished from the country. The leaders of the coup d'état formed a provisional government with Fonseca at its head, declared martial law, and effectively stamped out any armed resistance. In Jan. 1891, a constitutional assembly convened, adopted a Federal constitution and on Feb. 25, 1891 elected Fonseca constitutional president of the republic. But he had not the political skill to control the situation. He quarrelled with congress (May), dissolved it (Nov. 4), declared martial law and assumed dictatorial powers. He alienated his party by his arbitrary severity and by increasing issues of irredeemable paper money. When a revolt broke out in Rio Grande do Sul, which spread to other provinces, the army and navy forsook him; and on Nov. 23, 1891, he resigned his office and retired to private life. He died at Rio de Janeiro on Aug. 23, 1892. An able soldier, he lacked the essential flexibility and decision of the politician, and consequently did not leave that mark on posterity, which his high qualities deserved. (W. B. P.)

FONSECA, BAY or **GULF OF**, an arm of the Pacific ocean extending into Central America and bounded on the south by Nicaragua, on the east and north-east by Honduras and on the north and north-west by Salvador. It is about 50m. long and 30m. wide, and forms one of the finest natural harbours in the world. Surrounded by volcanic shores, with high sugar-loaf islands bespeckling its surface, it suggests to the observer that it is itself the crater of a vast volcano, the surroundings and the island-dotted surface of the bay forming a setting of unsurpassed natural beauty. The islands are green and some of them cultivated, and the distant volcanoes include Conchagua (3,800ft.) and Consequina (3,000ft.) at the entrance of the strait 18m. in width which connects the bay with the Pacific ocean. The islands at Conchagua, Mianguiri and the rocky "Farellones" guard the entrance and help to protect the harbour from the winds and waves of the Pacific. The largest islands in the bay itself are Sacate Grande, 7x4m., and El Tigre, on which the Pacific port of Honduras, Amapala (*q.v.*) is situated, and which rises to a height of 2,500ft. in a volcanic cone. The bay is bounded by a shore cut into innumerable inlets, some on the south and east, with volcanic lava shores, but north and north-eastward with sloping plains leading to the mountains, some miles distant. Fonseca bay was discovered in 1522 by Gil Gonzales de Avila and was named by him after his patron, that Archbishop Juan Fonseca who was the persecutor of Columbus. The bay is also known, locally, as the Gulf of Amapala or the Bay of Conchagua. Under the Bryan-Chamorro treaty of 1916, between the United States and Nicaragua, by the terms of which the United States acquired a perpetual option to the site of an interoceanic canal in Nicaraguan territory, Nicaragua also granted the United States the right to establish a naval base in Nicaraguan territory on Fonseca bay. This provision brought a prompt protest from Salvador, whose government held that such a naval base would constitute a threat against her sovereignty, and that the waters of Fonseca bay were not open sea but were the joint property of Salvador, Honduras and Nicaragua. This protest, inspired, it is now certain, by President Carranza of Mexico as a part of his Latin American activities against the United States during the World War, was carried to the Central American Court of Justice at San José, Costa Rica, and was one of the causes which led to the dissolution of the court (see CENTRAL AMERICA). (W. THO.)

FONT, the vessel used in churches to hold the water for Christian baptism. In the apostolic period baptism was administered at rivers or natural springs, Lat. *fons* (*cf.* Acts viii. 36), and no doubt the primitive form of the rite was by *immersion* in the water. *Infusion*—pouring water on the head of the neophyte—was early introduced into the west and north of Europe on account of the inconvenience of immersion, as well as its occasional danger; this form has never been countenanced in the Oriental churches. *Aspersión*, or sprinkling, was also admitted as valid, but recorded early examples of its use are rare (see BAPTISM). These different modes of administering baptism have caused corresponding changes in the receptacles for the water. After the cessation of persecution, when ritual and ornament began to develop openly, special buildings were erected for administering the rite of baptism. This was obviously necessary, for a large *piscina* (basin or tank) in which candidates could be immersed would occupy too much space of the church floor itself. These baptisteries consisted of tanks entered by steps (an ascent of three, and descent of four, to the water was the normal but not the invariable number) and covered with a domed chamber (see BAPTISTERY).

By the 9th century, however, the use of separate baptisteries had generally given place to that of fonts. The material of which these were made was stone, often decorative marble; as early as 524, however, the council of Lerida enacted that if a stone font were not procurable the presbyter was to provide a suitable vessel, to be used for the sacrament exclusively, which might be of any material. In the Eastern Church the font never became an important decorative article of church furniture.

Few if any fonts older than the 11th century survive. These are all of stone, except a few of lead; much less common are fonts of

cast bronze (a fine example, dated 1112, exists at the Church of St. Barthélemy, Liège). The most ancient are plain cylindrical bowls, with a circular—sometimes cruciform or quatrefoil—outline to the basin, either without support or with a single central pillar; occasionally there is more than one pillar. The basins are usually lined with lead to prevent absorption by the stone. The church of Efenechtyd, Denbigh, possesses an ancient font made of a single block of oak.

Fonts early began to be decorated with sculpture and relief. Arcading and interlacing work are common; so are symbol and pictorial representation. A very remarkable leaden font is preserved at Strasbourg, bearing reliefs representing scenes in the life of Christ. At Pont-à-Mousson on the Moselle are bas-reliefs of St. John the Baptist preaching, and baptizing Christ. Caryatides sometimes take the place of the pillars, and sculptured animals and grotesques of strange design not infrequently form the base. Most remarkable is the occasional persistence of pagan symbolism; an interesting example is the very ancient font from Ottrava, Sweden, which, among a series of Christian symbols and figures on its panels, bears a representation of Thor (see G. Stephens' brochure, *Thunor the Thunderer*).

In the 13th century octagonal fonts became commoner, and in the 14th and succeeding centuries they became the rule. In England no fonts can certainly be said to date before the Norman conquest, although it is possible that a few very rude examples, such as those of Washaway, Cornwall and Denton, Sussex, are actually of Saxon times; of course we cannot count as "Saxon fonts" those adapted from pre-Norman sculptured stones originally designed for other purposes, such as that at Dolton, Devonshire. On the other hand, Norman fonts are very common, and are often the sole surviving relics of the Norman parish church. They are circular or square, sometimes plain, but generally covered with carving of arcades, figures, foliage, etc. Some of the best examples of "Norman" fonts in England (such as the notable specimen in Winchester cathedral) were probably imported from Belgium. Fonts of the Perpendicular period are very common, and are generally raised upon steps and a lofty stem, which, together with the body of the font, are frequently richly ornamented with panelling. It was also the custom during this period to ornament the font with shields and coats of arms and other heraldic insignia, as at Herne, Kent.

In 1236 it was ordered by Edmund, archbishop of Canterbury, that baptismal fonts should be kept under lock and key, as a precaution against sorcery. The ordinary position in the church was and is near the entrance, usually to the left of the south door.

Green, *Baptismal Fonts, Classified and Illustrated* (1928). A large number of fine illustrations of fonts, principally of the earlier periods, will be found in the volumes of the *Reliquary* and *Illustrated Archaeologist*.

FONTAINE, PIERRE FRANÇOIS LÉONARD (1762-1853), French architect, was born at Pontoise on Sept. 20, 1762, and died in Paris on Oct. 10, 1853. Several of his family were distinguished architects. At the age of 16 he assisted the architect André in hydraulic works at l'Isle-Adam, and was allowed to copy his designs. In 1779 he went to Paris to study under Peyre the younger, and won the second prize at the Academy. With the pension received therefrom he went to Rome in 1785. During the French Revolution he took refuge in England; but later was employed by Bonaparte to restore the palace of Malmaison and thereafter executed the principal architectural works in Paris for Napoleon I., Louis XVIII. and Louis Philippe. He was employed with his friend, Percier, on the arch of the Carrousel, the restoration of the Palais-Royal, the grand staircase of the Louvre and the project for the union of the Louvre and the Tuileries. In 1812 he became a member of the Academy of Fine Arts and first architect to the emperor in 1813. With Percier he published the

following works: *Palais, maisons, et autres édifices de Rome moderne* (1802); *Descriptions de cérémonies et de fêtes* (1807 and 1810); *Recueil de décorations intérieures* (1812); *Choix des plus célèbres maisons de plaisance de Rome et des environs* (1809-13); *Résidences des souverains, Parallèle* (1833). *L'histoire du Palais Royal* was published by Fontaine alone.

See M. Fouché, *Percier et Fontaine* (1905).

FONTAINEBLEAU, a town of northern France, capital of an arrondissement in the department of Seine-et-Marne, 37 m. S.E. of Paris by rail. Pop. (1926) 12,180. It stands in the forest of Fontainebleau, nearly 2 m. from the left bank of the Seine. The Tambour mansion, and a portion of the cardinal of Ferrara's house, both of the 16th century, are still preserved. Fontainebleau is the seat of a subprefect and has a tribunal of first instance. It has quarries of sand and sandstone, saw-mills, and manufactories of porcelain and gloves. It is a summer resort, and the president of the Republic frequently resides in the palace, one of the largest of the royal residences of France, situated to the south-east of the town. The exact origin of the palace and of its name (Lat. *Fons Bleaudi*) are unknown, but the older château was used in the latter part of the 12th century by Louis VII. Francis I. caused most of the buildings of the Cour Ovale to be erected. After Francis I., Fontainebleau owes most to Henry IV., Louis XIII., Napoleon I., Louis XVIII., Louis Philippe and Napoleon III. The park covers about 200 acres and is traversed by a canal dating from the reign of Henry IV. On the north it is bordered by a vineyard producing white grapes.

The forest of Fontainebleau is one of the most beautiful wooded tracts in France, and has been for generations the haunt of landscape painters. It covers 42,200 ac., with a circumference of 56 m. Nearly a quarter of this area is of a rocky nature, and the quarries of sandstone supplied a large part of the paving of Paris. Oak, pine, beech, hornbeam and birch are the chief trees.

See Pfnor, *Monographie de Fontainebleau*, with text by Champollion Figeac (1866); *Guide artistique et historique au palais de Fontainebleau* (1889); E. Bourges, *Recherches sur Fontainebleau* (Fontainebleau, 1896); E. Plouchart, *Fontainebleau* (1925).

FONTAN, LOUIS MARIE (1801-1839), French man of letters, was born at Lorient. He wrote a number of plays, of which *Perkins Warbec* (1828), written in collaboration with MM. Halévy and Drouineau, was the most successful. He was repeatedly in trouble with the authorities under the Restoration, and spent some time in prison before the revolution of 1830 brought him release. His *Jeanne la folle*, performed in the same year, gained a success due perhaps mainly to sympathy with the author's political principles. A drama representing the trial of Marshal Ney, written in collaboration with Charles Dupenty, *Le Procès d'un maréchal de France* (printed 1831), was suppressed on the night of its production. Fontan died in Paris on Oct. 10, 1839.

A sympathetic portrait of Fontan as a prisoner, and an analysis of his principal works, are to be found in Jules Janin's *Histoire de la littérature dramatique*, vol. i.

FONTANA, DOMENICO (1543-1607), Italian architect and mechanician, was born at Mili on the Lake of Como in 1543, and died at Naples in 1607. After training in mathematics he went to Rome to study architecture, and entered the service of Cardinal Montalto (afterwards Sixtus V.), for whom he erected a chapel in the church of Santa Maria Maggiore and the Villa Negroni. On the election of Sixtus V., Fontana became his chief architect. Among his works were the Laleian palace, the palace of Monte Cavallo (the Quirinal), the Vatican library, etc. The undertaking which brought him the highest repute was the removal of the Egyptian obelisk (brought to Rome in the reign of Caligula) from the place where it lay in the Circus of the Vatican and its erection in front of St. Peter's in 1586. After the death of Sixtus V., Fontana was accused of misappropriating public moneys, and was dismissed from his post in 1592 by Clement VIII. He then became architect at Naples to the viceroy, the count of Miranda, and built the royal palace. His projected new harbour and bridge was carried out after his death. The account of the removal of the obelisk (Rome, 1590) is his only literary

work. His son Giulio Cesare succeeded him as royal architect at Naples, the university there being his best-known building.

FONTANA, LAVINIA (1552-1614), Italian portrait-painter, was the daughter of Prospero Fontana (q.v.). She was greatly employed by the ladies of Bologna, and, going thence to Rome, painted the likenesses of many illustrious personages. She enjoyed the patronage of the family (Buoncampagni) of Pope Gregory XIII. The Roman ladies, from the days of this pontiff to those of Paul V., elected in 1605, showed no less favour to Lavinia than their Bolognese sisters had done. In her subject pictures she was not so successful. Examples of her work are to be seen at Bologna, Rome, Florence, Venice, Milan; the "Virgin lifting a veil from the sleeping infant Christ," in the Escorial, Madrid; and the "Queen of Sheba," a group of the Mantua courts, in the Dublin museum. Two self-portraits are at the Pitti, Florence, and one in the Academy of St. Luke, Rome. Her husband, whose name is given as Paola Zappi Giovanni of Imola, belonged to a distinguished family. He studied painting with Lavinia's father, and is said to have painted the draperies in many of Lavinia's pictures. She was elected into the Academy of Rome, and died in that city in 1614.

FONTANA, PROSPERO (1512-1597), Italian painter, was born in Bologna, and became a pupil of Innocenzo Francucci da Imola. He afterwards worked for Vasari and Perino del Vaga in Genoa, Florence and Rome. He has left a large quantity of work in Bologna where he lived after 1540. A representative work of his early period is the "Entombment" in the Bologna Pinacoteca, painted under the influence of his first master and comparatively careful in execution. To his later period belongs the "St. Alessis distributing Alms," in S. Giacomo Maggiore at Bologna (1576), with many figures in architectural setting, in the mannered style of Vasari's pupils. In portraiture he was outshone by his daughter and pupil, Lavinia. He died in Bologna in 1597.

FONTANE, THEODOR (1819-1898), German poet and novelist, was born at Neu-Ruppin on Dec. 30, 1819. He made repeated visits to England, interesting himself in old English ballads, and as the first fruits of his tours published *Ein Sommer in London* (1854); *Aus England, Studien und Briefe* (1860) and *Jenseit des Tweed, Bilder und Briefe aus Schottland* (1860), and a volume of ballads *Männer und Helden* (1860). Fontane ranks with Uhland as one of the great ballad writers of the 19th century. He drew his material from English, Scottish and above all Prussian sources; sometimes, as in *Die Brück'am Tay* from contemporary events. Among the most famous are *Archibald Douglas*, *Schloss Eger*, and one on "der alte Dessauer." Fontane was particularly attached to his native Mark of Brandenburg; the fascination which it had for him may be seen in his delightfully picturesque *Wanderungen durch die Mark Brandenburg* (1862-82, 4 vols.). In 1870 he was for three months a prisoner of war at Vaucouleurs. His fine historical romance *Vor dem Sturm* (1878) was followed by a series of novels of contemporary life: *Irrungen, Wirrungen* (1888); *Stine* (1890); *Unwiederbringlich* (1891); *Effi Briest* (1895); *Der Stechlin* (1899), in which Fontane adapted the realistic methods and social criticism of contemporary French fiction to the conditions of Prussian life. He died on Sept. 20, 1898 at Berlin.

Fontane's other works include: *Kriegsgefangen, Erlebtes 1870* (1871); *Der Krieg gegen Frankreich 1870-71* (1874-76). Fontane's *Gesammelte Romane und Erzählungen* were published in 12 vols. (1890-91, 2nd ed., 1905). For his life see the autobiographical works *Meine Kinderjahre* (1894), and *Von Zwanzig bis Dreissig* (1898), also *Briefe an seine Familie* (1905). See also monographs by F. Servaes (1900), Zillman (Stuttgart, 1919), Wandrey (Munich, 1919), and K. Hayens (London, 1920).

FONTANES, LOUIS, MARQUIS DE (1757-1821), French poet and politician, was born at Niort (Deux Sèvres) on March 6, 1757. He wrote a number of poems, including a version of Pope's *Essay on Man*. Fontanes drew up the protest of the citizens of Lyons against Collot d'Herbois, and was for some time in hiding. On the fall of Robespierre he was made professor of literature in the *École Centrale des Quatre-Nations*, and he was one of the original members of the Institute. He was exiled by the Directory and made his way to London, where he was associated with

Chateaubriand. He soon returned to France, and his admiration for Napoleon, who commissioned him to write an *éloge* on Washington, secured his return to the Institute and his political promotion. He was president of the legislative chamber from 1804 to 1810. Fontanes has been accused of servility to Napoleon, but he remonstrated with him on the judicial murder of the duc d'Enghien, and as grand master of the university of Paris (1808-1815) he supported monarchical principles. He was made a marquis in 1817. He died on March 17, 1821, in Paris.

See his *Oeuvres* (2 vols. 1839), ed. Sainte-Beuve.

FONTENAY-LE-COMTE, town of western France, capital of an arrondissement in the department of Vendée 30 m. N.E. of La Rochelle by rail. Pop. (1926), town, 7,435; commune, 9,423.

Fontenay existed in the time of the Gauls. The affix of "comte" was added when it was given to the count of Poitou, under whom it became capital of Bas-Poitou. Ceded to the English by the treaty of Brétigny in 1360 it was retaken in 1372 by Duguesclin. It suffered repeated capture during the Religious Wars of the 16th century, was dismantled in 1621 and was occupied both by the republicans and the Vendéans in the war of 1793. From 1790 to 1806 it was capital of the department of Vendée. Fontenay, a straggling town, is situated on both banks of the Vendée, at the head of navigation. The church of Notre Dame (15th-18th cent.) is rich in sculpture, and there are several old houses. The Hôtel de Terre Neuve (1595-1600) contains collections of furniture and tapestry. The Fontaine des Quatre-Tias, given to the town by King Francis I., commemorates the birth of many prominent men. Fontenay-Le-Comte is the seat of a subprefect and has a tribunal of first instance. It manufactures felt hats, oil and soap; timber-sawing, flour-milling and tanning are also carried on. There is trade in grain, fruit, horses, mules, timber, etc.

FONTENELLE, BERNARD LE BOVIER DE (1657-1757), French author, was born at Rouen, on Feb. 11, 1657. He died in Paris, on Jan. 9, 1757, having thus very nearly attained the age of 100 years. His father was an advocate settled in Rouen, his mother a sister of the two Corneille. He was educated at the college of the Jesuits in his native city, and then qualified as an advocate. He visited Paris from time to time and established relations with the abbé de Saint Pierre, the abbé Vertot and the mathematician Pierre Varignon. His tragedy *Aspar* (1680) was a complete failure. His opera of *Thétis et Pélée* (1689) was highly praised by Voltaire, but none of his dramatic works kept the stage. His *Poésies pastorales* (1688) show great purity of diction and occasional felicity of expression.

Real success came with his collection of entertaining stories, *Lettres galantes du chevalier d'Her . . .*, published anonymously in 1685. In 1686 appeared his famous allegory of Rome and Geneva, slightly disguised as the rival princesses Mæo and Eenege, in the *Relation de l'île de Bornéo*. His most famous works are *Nouveaux Dialogues des morts* (1683) and *Entretiens sur la pluralité des mondes* (1686). His object was to popularize among his countrymen the astronomical theories of Descartes, and he was a most ingenious and successful expositor.

In 1687 Fontenelle removed to Paris; and in the same year he published his *Histoire des oracles*, consisting of two essays, the first of which was designed to prove that oracles were not given by the supernatural agency of demons, and the second that they did not cease with the birth of Christ. In his *Digression sur les anciens et les modernes* (1688) he took the modern side in the controversy; his *Doutes sur le système physique des causes occasionnelles* (against Malebranche) appeared shortly afterwards.

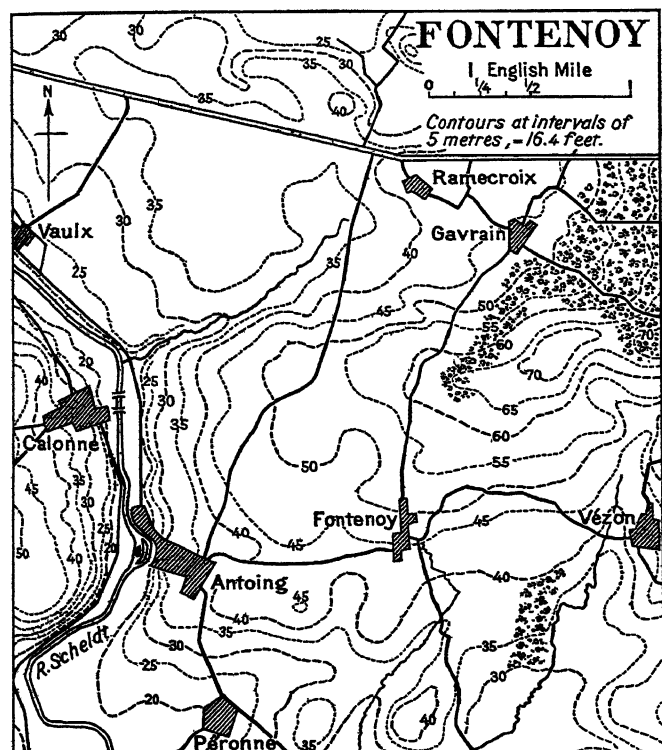

In 1691 he was received into the French Academy in spite of the determined efforts of the partisans of the ancients in this quarrel, especially of Racine and Boileau, who on four previous occasions had secured his rejection. He consequently was admitted a member both of the Academy of Inscriptions and of the Academy of Sciences; and in 1697 he became perpetual secretary to the latter body. This office he actually held for the long period of 42 years; and it was in this official capacity that he wrote the *Histoire du renouvellement de l'Académie des Sciences* (3 vols., 1708, 1717, 1722) containing extracts and analyses of the proceedings, and also the *éloges* of the members, written with great

simplicity and delicacy. The other important works of Fontenelle are his *Eléments de la géométrie de l'infini* (1727), and his *Apologie des tourbillons* (1752).

There have been several collective editions of Fontenelle's works, the first being printed in 3 vols. at the Hague in 1728-29. The best is that of Paris, 8 vols., 1790. Some of his separate works have been very frequently reprinted and also translated. The *Pluralité des mondes* was translated into modern Greek in 1794. Sainte-Beuve has an interesting essay on Fontenelle, with several useful references, in the *Causeries du lundi*, vol. iii. See also A. F. Villemain, *Tableau de la littérature française au XVIII^e siècle* (1864); the abbé Trublet, *Mémoires pour servir à l'histoire de la vie et des ouvrages de M. de Fontenelle* (1759); A. Laborde-Milaa, *Fontenelle* (1905), in the "Grands écrivains français" series; and L. Maigron, *Fontenelle, l'homme, l'oeuvre, l'influence* (1906).

FONTENROY, a village of Belgium, in the province of Henegau, about 4m. S.E. of Tournai, famous as the scene of the battle of Fontenoy, in which on May 11, 1745, the French army under Marshal Saxe defeated the Anglo-Allied army under the duke of Cumberland. The object of the French (see also AUSTRIAN SUCCESSION, WAR OF THE) was to cover the siege of the then important fortress of Tournai; that of the Allies, who slowly advanced from the east, to relieve it. Informed of the impending attack, Louis XV., with the dauphin, came with all speed to witness the operations, and by his presence to give Saxe, who was in bad health and beset with private enemies, the support necessary to enable him to command effectively. Under Cumberland served the Austrian field-marshal Königsegg, and, at the head of the Dutch contingent, the prince of Waldeck.

The right of the French position (see map) rested on the river at Antoing, which village was fortified and garrisoned; between Antoing and Fontenoy three square redoubts were constructed; and Fontenoy itself was put in a complete state of defence. On

PLAN OF THE BATTLE OF FONTENROY, MAY 11TH, 1745

the left rear of this line, and separated from Fontenoy by some furlongs of open ground, another redoubt was made at the corner of the wood of Barry and a fifth towards Gavrain. The infantry was arrayed in deployed lines behind the Antoing-Fontenoy redoubts and the low ridge between Fontenoy and the wood; behind them was the cavalry. Marshal Saxe himself, who was suffering from dropsy to such an extent that he was unable to mount his horse, slept in a wicker chariot in the midst of the troops. At early dawn of May 11, the Anglo-Hanoverian army with the

Austrian contingent formed up in front of Vézon, facing towards Fontenoy and the wood, while the Dutch on their left extended the general line to Péronne. The total force was 46,000 against 52,000 whom Saxe could actually put into the line of battle.

It was resolved that the Dutch should attack the front Antoing-Fontenoy, while Cumberland should deliver a flank attack against Fontenoy and all in rear of it, by way of the open ground between Fontenoy and the wood. A great cavalry attack round the wood was projected but had to be given up, as in the late evening of the 10th the Allies' light cavalry drew fire from its southern edge. Cumberland then ordered his cavalry commander to form a screen facing Fontenoy, so as to cover the formation of the infantry. On the morning of the 11th another and most important modification had to be made. The advance was beginning when the redoubt at the corner of the wood became visible. Cumberland hastily told off Brigadier James Ingoldsby to storm this redoubt which, crossing its fire with that of Fontenoy, seemed absolutely to inhibit the development of the flank attack. At 6 A.M. the brigade moved off, but it was irresolutely handled; and after waiting as long as possible, the British and Hanoverian cavalry rode forward and extended in the plain, becoming the target for a furious cannonade which drove them back. Thereupon Sir John (Lord) Ligonier, whose deployment the squadrons were to have covered, let them pass to the rear, and pushed the British infantry forward through the lanes, each unit on reaching open ground covering the exit and deployment of the one in the rear, all under the French cannonade. This went on for two hours, and save that it showed the magnificent discipline of the British and Hanoverian regiments, was a bad prelude to the real attack.

It was now 9 A.M., and while the guns from the wood redoubt battered the upright ranks of the Allies, Ingoldsby's brigade was huddled together, motionless, on the right. Cumberland himself galloped thither, and under his reproaches Ingoldsby lost the last remnants of self-possession. To Ligonier's aide-de-camp, who delivered soon afterwards a bitterly formal order to advance, Ingoldsby sullenly replied that the duke's orders were for him to advance in line with Ligonier's main body. By now, too, the Dutch advance against Antoing-Fontenoy had collapsed.

But on the right the cannonade and the blunders together had roused a stern and almost blind anger in the leaders and the men they led. Ingoldsby was wounded, and his successor, the Hanoverian general Zastrow, gave up the right attack and brought his battalions into the main body. Meantime the young duke and the old Austrian field-marshal had agreed to take all risks and to storm through between Fontenoy and the wood redoubt, and had launched the great attack, one of the most celebrated in the history of war. The English infantry was in two lines. The Hanoverians on their left, owing to want of space, were compelled to file into third line behind the redcoats, and on their outer flanks were the battalions that had been with Ingoldsby. A few guns, man-drawn, accompanied the assaulting mass, and the cavalry followed. The column may have numbered 14,000 infantry. All the infantry battalions closed on their centre, the normal three ranks becoming six. (If the proper distances between lines were preserved, the mass must have formed an oblong about 500yd. x 600yd.).

The duke of Cumberland placed himself at the head of the front line and gave the signal to advance. Slowly and in parade order, drums beating and colours flying, the mass advanced, straight up the gentle slope, which was swept everywhere by the flanking artillery of the defence. When the first line reached the low crest, the fire became a full enfilade from both sides, and at the same moment the enemy's horse and foot became visible beyond. A brief pause ensued, and the front gradually contracted as regiments shouldered inwards to avoid the fire. Then the French advanced, and the Guards Brigade and the Gardes Françaises met face to face. Captain Lord Charles Hay, lieutenant of the First (Grenadier) Guards, suddenly ran in front of the line, took off his hat to the enemy and drank to them from a pocket flask, shouting a taunt, "We hope you will stand till we come up to you, and not swim the river as you did at Dettingen," then, turning to his own men, he called for three cheers. The astonished French officers returned the salute and gave a ragged counter-cheer.

Whether or not the French, as legend states, were asked and refused to fire first, the whole British line fired one tremendous series of volleys by companies. Fifty officers and 760 men of the three foremost French regiments fell at once, and at so appalling a loss the remnant broke and fled. Three hundred paces farther on stood the second line of the French, and slowly the mass advanced, firing regular volleys. It was now well inside the French position, and no longer felt the enfilade fire that swept the crest it had passed over. Spasmodic counter-attacks on its flanks were repelled but these gained a few precious minutes for the French. It was the crisis of the battle. The king, though the court meditated flight, stood steady with the dauphin at his side—Fontenoy was the one great day of Louis XV.'s life—and Saxe, ill as he was, mounted his horse to collect his cavalry for a charge. The British and Hanoverians were now at a standstill. More and heavier counter-strokes were repulsed, but no progress was made; their cavalry was unable to get to the front, and Saxe was by now thinking of victory. Captain Isnard of the Touraine regiment suggested artillery to batter the face of the square, preparatory to a final charge. The nearest guns were planted in front of the assailants, and used with effect. The infantry led by Löwendahl, fastened itself on the sides of the square. On the front, waiting for the cannon to do its work, were the Maison du Roi, the Gendarmierie and all the light cavalry. The left wing of the Allies was still inactive, and French troops were brought up from Antoining and Fontenoy to support the final blow, about 2 P.M. In eight minutes the square was broken. As the infantry retired across the plain in small stubborn groups all attempts to close with them were repulsed by the terrible volleys, and they regained the broken ground about Véron, whence they had come. Cumberland himself and all the senior generals remained with the rearguard.

The losses at Fontenoy were exceedingly severe in the units really engaged. Eight out of nineteen regiments of British infantry lost over 200 men, two of these more than 300. The Hanoverian regiments suffered as heavily in proportion. The total loss was about 7,500, that of the French 7,200.

Fontenoy was in the 18th century what the attack of the Prussian Guards at St. Privat was in the next, a *locus classicus* for military theorists. But the technical features of the battle are completely overshadowed by its epic interest.

FONTEVRAULT or **FONTEVRAUD** (Lat. *Fons Ebrauld*), a town of western France, in the department of Maine-et-Loire, 10 m. S.E. of Saumur by road, near the confluence of the Loire and Vienne. Pop. (1926) 1,121. The interest of the place centres in its abbey, since 1804 utilized and abused as a convict prison. The church (12th century) has a beautiful nave formerly covered by four cupolas destroyed in 1816. There is a fifth cupola above the crossing. In a chapel in the south transept are the effigies of Henry II. of England, of his wife Eleanor of Guienne, of Richard I. of England and of Isabella of Angoulême, wife of John of England—Eleanor's being of oak and the rest of stone. Cloister, refectory and chapter-house date from the 16th century. The second court of the abbey contains the Tour d'Évrauld (12th century), long called *chapelle funéraire*, but in reality the old kitchen. Details and diagrams will be found in Viollet-le-Duc's *Dictionnaire de l'architecture*. There are three stories, the whole being surmounted by a pyramidal structure.

The *Order of Fontevrauld* was founded about 1100 by Robert of Arbrissel. The establishment was a double monastery, containing a nunnery of 300 nuns and a monastery of 200 monks, separated completely so that no communication was allowed except in the church; there were, moreover, a hospital for 120 lepers and other sick, and a penitentiary for fallen women, both worked by the nuns. The basis of the life was the Benedictine rule; the abbess ruled the monks as well as the nuns. At the beginning the order had a great vogue, and at the time of Robert's death, 1117, there were several monasteries and 3,000 nuns; afterwards the number of monasteries reached 57, all organized on the same plan. The institute never thrived out of France; there were attempts to introduce it into Spain and England: in England there were three houses—at Ambresbury (Amesbury in Wiltshire), Nuneaton, and Westwood in Worcestershire. The nuns in England as in

France were recruited from the highest families, and the abbess of Fontevrauld, who was the superior-general of the whole order, was usually of the royal family of France.

See P. Hélyot, *Hist. des ordres religieux* (1718); Max Heimbucher, *Orden und Kongregationen* (1907); the arts. "Fontevraud" in *Wetzer and Welte, Kirchenlexicon* (ed. 2), and in Herzog-Hauck, *Realencyklopädie* (ed. 3); Édouard, *Fontevrauld et ses monuments* (1875); for the later history see art. by Edmund Bishop in *Downside Review* (1886).

FOOCHOW, a treaty port of China and the capital of the province of Fukien. Its population, estimated at 625,000, ranks it among the larger cities of China. The position of Foochow near the mouth of the Min river (26° 7' N., 119° 20' E.), which gathers up the drainage of fully two-thirds of Fukien, marks it out as the capital of a province which is separated from the rest of China by high forested ridges and to some extent constitutes an independent regional division of China. This remoteness from other centres of population, and the separateness of the provincial life of Fukien, was the reason, for example, for the foundation at Foochow in 1921 of the Fukien Christian university, one of the five Union universities of China. But although its communications are virtually limited on the landward side to the province, Foochow lies on the sea route which was developed early from the South China coast and by way of the Spice islands to India and ultimately to Europe. It was because of this position that Foochow was created one of the original five treaty ports by the Treaty of Nanking in 1842. Foochow does not seem to have participated much in the earlier phases of this maritime commerce but with the development of the tea trade, especially in the early 19th century, it grew rapidly to be one of the foremost Chinese tea ports.

At its most prosperous period it exported not only the teas of Fukien but also teas brought over difficult mountain tracks from the interior provinces. Eventually these interior supplies were cut off by the opening up of the Yangtze route to foreign trade and with the decline in the China tea trade as a whole Foochow suffered heavily. Much, too, of its camphor trade has been lost to Formosa. Foochow is therefore engaged in adjusting its trade to changed conditions. The bulk of its foreign trade now passes through one or other of the entrepôts of Hongkong or Shanghai, each with a vast hinterland behind it. Some compensation is being found in the increase of the coastwise trade which is concerned with such articles as paper, canned foodstuffs, bamboo shoots, soap and the like. The industries of the city are engaged mainly in the production of these goods.

The total trade of the port in 1926 was Hk. Tls. 34,284,967 and it then stood 19th among Chinese ports. The navigation of the Min river is being improved (Foochow stands 35 miles from its mouth) so that vessels drawing 17 ft. of water will be able to reach the city instead of, as hitherto, having to discharge at the Pagoda anchorage, ten miles downstream. But Foochow is not likely to regain the importance it possessed when the tea trade was at its height and its significance will lie in coastwise rather than in international trade.

FOOD, the general term for what is eaten by man and other creatures for the sustenance of life. The scientific aspect of human food is dealt with under **NUTRITION**; **DIET** and **DIETETICS**.

Infancy.—The influence of a normal diet upon the health of man (we exclude here the question of diet in illness, which must depend on the abnormal conditions existing) begins at the earliest stage of his life. No food has as yet been found so suitable for the young of all animals as their mother's milk. This, however, has not been from want of seeking. Baron Justus von Liebig, as the result of his chemical researches, introduced a "food for infants," which in more modern days has been followed by a multiplication of patent foods. A close imitation of human milk may also be made by adding to fresh cow's milk half its bulk of soft water, in each pint of which has been mixed a heaped-up teaspoonful of powdered "sugar of milk" and a pinch of phosphate of lime. These artificial substitutes for the natural nutriment have their value where for any reason it is not available. The wholesomest food, however, for the first six months is certainly mother's milk alone. It is only when the teeth are on their way

to the front, as shown by dribbling, that the parotid glands secrete an active saliva capable of digesting starchy foods. Till then anything but milk must be given tentatively, and considered in the light of a means of education for its future mode of nutrition.

The time for weaning should be fixed partly by the child's age, partly by the growth of the teeth. The first group of teeth usually consists of the lower central front teeth, which may appear any

BY COURTESY OF SCIENCE SERVICE, WASHINGTON

PERCENTAGES OF WATER IN VARIOUS KINDS OF COMMON FOODS

time during the sixth and seventh month. The mother may then begin to diminish the number of suckling times; and by a month she can have reduced them to twice a day, so as to be ready when the second group makes its way through the upper front gums, to cut off the supply altogether. The third group, the lateral incisors and first grinders, usually after the first anniversary of birth, give notice that solid food can be chewed. But it is prudent to let dairy milk form a considerable portion of the fare till the eye-teeth are cut, which seldom happens till the 18th or 20th month.
